**About** ............................................................................................................... 1

**Chapter 1: Getting started with MATLAB Language** ........................................... 2

Versions ...................................................................................................................... 2

See also: MATLAB release history on Wikipedia. ................................................. 3

Examples ..................................................................................................................... 4

Hello World ................................................................................................................. 4

Matrices and Arrays ................................................................................................... 4

Indexing matrices and arrays .................................................................................... 6

Subscript indexing ........................................................................................................ 6

Linear indexing ........................................................................................................... 7

Logical indexing ........................................................................................................ 9

More on indexing ....................................................................................................... 10

Helping yourself ....................................................................................................... 12

Reading Input & Writing Output ................................................................................ 12

Cell arrays ................................................................................................................ 14

Scripts and Functions ............................................................................................... 15

Data Types ................................................................................................................ 16

Anonymous functions and function handles ......................................................... 19

**Basics** .................................................................................................................... 19

The @ operator ....................................................................................................... 20

Custom anonymous functions ................................................................................. 20

  Anonymous functions of one variable ................................................................. 20

  Anonymous functions of more than one variable ............................................. 21

  Parameterizing anonymous functions .............................................................. 21

  Input arguments to an anonymous function do not refer to workspace variables. 22

  Anonymous functions are stored in variables ..................................................... 22

**Advanced use** ........................................................................................................ 22

  Passing function handles to other functions ..................................................... 22

  Using bsxfun, cellfun and similar functions with anonymous functions .......... 23

**Chapter 2: Common mistakes and errors** ............................................................ 25
Examples ........................................................................................................................................... 25

Do not name a variable with an existing function name................................................................. 25

What you see is NOT what you get: char vs cellstring in the command window ......................... 25

The transpose operators .................................................................................................................. 26

Undefined Function or Method X for Input Arguments of Type Y .................................................. 27

That function was introduced after your current version of MATLAB ........................................ 27

You don't have that toolbox! ............................................................................................................ 27

MATLAB cannot locate the function .............................................................................................. 28

Be aware of floating point inaccuracy ............................................................................................ 28

Examples: Floating point comparison done WRONG: ................................................................. 29

Example: Floating point comparison done RIGHT: ........................................................................ 29

Syntax ............................................................................................................................................. 37

Parameters ...................................................................................................................................... 37

Examples ........................................................................................................................................ 37

IF condition ................................................................................................................................... 37

IF-ELSE condition ......................................................................................................................... 38

IF-ELSEIF condition ....................................................................................................................... 38
## Nested conditions

Chapter 4: Controlling Subplot coloring in Matlab

### Introduction

### Remarks

### Examples

### How it's done

Chapter 5: Debugging

### Syntax

### Parameters

### Examples

### Working with Breakpoints

### Definition

#### Breakpoints in MATLAB

### Motivation

### Types of Breakpoints

### Placing Breakpoints

### Disabling and Re-enabling Breakpoints

### Removing Breakpoints

### Resuming Execution

### Debugging Java code invoked by MATLAB

### Overview

### MATLAB end

### Windows:

### Debugger end

### IntelliJ IDEA

Chapter 6: Documenting functions

### Remarks

### Examples

#### Simple Function Documentation

#### Local Function Documentation

#### Obtaining a function signature
Implement a simple Fourier Transform in Matlab ................................................................. 79
Inverse Fourier Transforms ................................................................................................. 80
Images and multidimensional FTs ......................................................................................... 82
Zero filling ............................................................................................................................. 82
Hints, tips, 3D and beyond .................................................................................................... 86

Chapter 11: Functions ............................................................................................................. 88
Examples ................................................................................................................................. 88
Base example .......................................................................................................................... 88
Multiple outputs ...................................................................................................................... 88
nargin, nargout ......................................................................................................................... 89

Chapter 12: Graphics: 2D and 3D Transformations ................................................................. 91
Examples ................................................................................................................................. 91
2D Transformations .................................................................................................................. 91

Chapter 13: Graphics: 2D Line Plots ..................................................................................... 94
Syntax ....................................................................................................................................... 94
Parameters ............................................................................................................................... 94
Remarks .................................................................................................................................... 94
Examples ................................................................................................................................. 94
Multiple lines in a single plot ....................................................................................................... 94
Split line with NaNs ................................................................................................................... 95
Custom colour and line style orders ....................................................................................... 96

Chapter 14: Image processing ................................................................................................ 100
Examples ................................................................................................................................. 100
Basic image I/O ......................................................................................................................... 100
Retrieve Images from the Internet .......................................................................................... 100
Filtering Using a 2D FFT .......................................................................................................... 100
Image Filtering .......................................................................................................................... 101
Measuring Properties of Connected Regions .......................................................................... 103

Chapter 15: Initializing Matrices or arrays ............................................................................ 106
Introduction .............................................................................................................................. 106
Syntax ....................................................................................................................................... 106
Parameters ............................................................................................................................... 106
Create Unique Name for Temporary File .......................................................... 130
Use validateattributes .................................................................................. 132
Block Comment Operator .............................................................................. 136

Chapter 20: MATLAB User Interfaces .......................................................... 139
Examples ......................................................................................................... 139
Passing Data Around User Interface .............................................................. 139

 GUIDATA ......................................................................................................... 139
setappdata/getappdata ............................................................................... 139
UserData ....................................................................................................... 140

Nested Functions ........................................................................................ 141
Explicit input arguments ............................................................................. 141
Making a button in your UI that pauses callback execution ......................... 142
Passing data around using the "handles" structure ........................................ 143
Performance Issues when Passing Data Around User Interface ................. 144

Chapter 21: Matrix decompositions .............................................................. 146
Syntax .......................................................................................................... 146
Examples ....................................................................................................... 146
Cholesky decomposition ................................................................................ 146
QR decomposition ......................................................................................... 146
LU decomposition ........................................................................................ 147
Schur decomposition .................................................................................... 148
Singular value decomposition ...................................................................... 149

Chapter 22: Multithreading ........................................................................... 150
Examples ....................................................................................................... 150
Using parfor to parallelize a loop ................................................................. 150
When to use parfor ....................................................................................... 150
Executing commands in parallel using a "Single Program, Multiple Data" (SPMD) statement ....................................................... 151
Using the batch command to do various computations in parallel .......... 152

Chapter 23: Object-Oriented Programming .................................................. 153
Examples ....................................................................................................... 153
Defining a class ............................................................................................. 153
Chapter 29: Undocumented Features ................................................................. 179
Remarks .................................................................................................................. 179
Examples .................................................................................................................. 179
  C++ compatible helper functions ................................................................. 179
  Color-coded 2D line plots with color data in third dimension .................. 179
  Semi-transparent markers in line and scatter plots ...................................... 180
  Contour Plots - Customise the Text Labels ..................................................... 182
  Appending / adding entries to an existing legend ........................................... 183
  Scatter plot jitter ............................................................................................... 184

Chapter 30: Usage of `accumarray()` Function .................................................. 186
Introduction ........................................................................................................... 186
Syntax .................................................................................................................... 186
Parameters ............................................................................................................ 186
Remarks .................................................................................................................. 186
References: ............................................................................................................. 186
Examples ................................................................................................................ 187
  Finding the maximum value among elements grouped by another vector .... 187
  Apply Filter to Image Patches and Set Each Pixel as the Mean of the Result of Each Patch .................................................. 187

Chapter 31: Useful tricks ....................................................................................... 189
Examples ................................................................................................................ 189
  Useful functions that operate on cells and arrays ........................................... 189
  Code Folding Preferences ................................................................................. 191
  Extract figure data ............................................................................................. 194
  Functional Programming using Anonymous Functions ............................... 195
  Save multiple figures to the same .fig file ....................................................... 196
  Comment blocks ............................................................................................... 196

Chapter 32: Using functions with logical output ............................................... 198
Examples ................................................................................................................ 198
  All and Any with empty arrays ....................................................................... 198

Chapter 33: Using serial ports ............................................................................. 199
Introduction ........................................................................................................... 199
Parameters ............................................................................................................. 199
Examples .................................................................................................................. 199

Creating a serial port on Mac/Linux/Windows ......................................................... 199

Reading from the serial port .................................................................................. 200

Closing a serial port even if lost, deleted or overwritten ...................................... 200

Writing to the serial port ....................................................................................... 200

Choosing your communication mode .................................................................... 201

Mode 1: Synchronous (Master/Slave) .................................................................... 201

Mode 2: Asynchronous .......................................................................................... 202

Mode 3: Streaming (Real time) ................................................................................ 203

Automatically processing data received from a serial port ...................................... 204

Chapter 34: Vectorization ..................................................................................... 206

Examples ................................................................................................................. 206

Element-wise operations ....................................................................................... 206

Sum, mean, prod & co .......................................................................................... 206

Use of bsxfun ........................................................................................................ 207

Syntax ..................................................................................................................... 208

Remarks ................................................................................................................. 209

Logical Masking .................................................................................................... 209

Implicit array expansion (broadcasting) [R2016b] .................................................... 210

Examples of compatible sizes: .............................................................................. 211

Examples of incompatible sizes: ............................................................................ 211

Get the value of a function of two or more arguments ......................................... 212

Examples

Hello World

Open a new blank document in the MATLAB Editor (in recent versions of MATLAB, do this by selecting the Home tab of the toolstrip, and clicking on New Script). The default keyboard shortcut to create a new script is Ctrl-n.

Alternatively, typing `edit myscriptname.m` will open the file `myscriptname.m` for editing, or offer to create the file if it does not exist on the MATLAB path.

In the editor, type the following:

```matlab
disp('Hello, World!');
```

Select the Editor tab of the toolstrip, and click Save As. Save the document to a file in the current directory called `helloworld.m`. Saving an untitled file will bring up a dialog box to name the file.

In the MATLAB Command Window, type the following:

```matlab
>> helloworld
```

You should see the following response in the MATLAB Command Window:

```
Hello, World!
```

We see that in the Command Window, we are able to type the names of functions or script files that we have written, or that are shipped with MATLAB, to run them.

Here, we have run the 'helloworld' script. Notice that typing the extension (.m) is unnecessary. The instructions held in the script file are executed by MATLAB, here printing 'Hello, World!' using the `disp` function.

Script files can be written in this way to save a series of commands for later (re)use.

Matrices and Arrays

In MATLAB, the most basic data type is the numeric array. It can be a scalar, a 1-D vector, a 2-D matrix, or an N-D multidimensional array.

```matlab
% a 1-by-1 scalar value
x = 1;
```

To create a row vector, enter the elements inside brackets, separated by spaces or commas:

```matlab
% a 1-by-4 row vector
v = [1, 2, 3, 4];
v = [1 2 3 4];
```
To create a column vector, separate the elements with semicolons:

```matlab
% a 4-by-1 column vector
v = [1; 2; 3; 4];
```

To create a matrix, we enter the rows as before separated by semicolons:

```matlab
% a 2 row-by-4 column matrix
M = [1 2 3 4; 5 6 7 8];

% a 4 row-by-2 column matrix
M = [1 2; 4 5; 6 7; 8 9];
```

Notice you cannot create a matrix with unequal row / column size. All rows must be the same length, and all columns must be the same length:

```matlab
% an unequal row / column matrix
M = [1 2 3; 4 5 6 7]; % This is not valid and will return an error

% another unequal row / column matrix
M = [1 2 3; 4 5; 6 7 8; 9 10]; % This is not valid and will return an error
```

To transpose a vector or a matrix, we use the .'-operator, or the ' operator to take its Hermitian conjugate, which is the complex conjugate of its transpose. For real matrices, these two are the same:

```matlab
% create a row vector and transpose it into a column vector
v = [1 2 3 4].'; % v is equal to [1; 2; 3; 4];

% create a 2-by-4 matrix and transpose it to get a 4-by-2 matrix
M = [1 2 3 4; 5 6 7 8].'; % M is equal to [1 5; 2 6; 3 7; 4 8]

% transpose a vector or matrix stored as a variable
A = [1 2; 3 4];
B = A.'; % B is equal to [1 3; 2 4]
```

For arrays of more than two-dimensions, there is no direct language syntax to enter them literally. Instead we must use functions to construct them (such as `ones`, `zeros`, `rand`) or by manipulating other arrays (using functions such as `cat`, `reshape`, `permute`). Some examples:

```matlab
% a 5-by-2-by-4-by-3 array (4-dimensions)
arr = ones(5, 2, 4, 3);

% a 2-by-3-by-2 array (3-dimensions)
arr = cat(3, [1 2 3; 4 5 6], [7 8 9; 0 1 2]);

% a 5-by-4-by-3-by-2 (4-dimensions)
arr = reshape(1:120, [5 4 3 2]);
```
Indexing matrices and arrays

MATLAB allows for several methods to index (access) elements of matrices and arrays:

- **Subscript indexing** - where you specify the position of the elements you want in each dimension of the matrix separately.
- **Linear indexing** - where the matrix is treated as a vector, no matter its dimensions. That means, you specify each position in the matrix with a single number.
- **Logical indexing** - where you use a logical matrix (and matrix of true and false values) with the identical dimensions of the matrix you are trying to index as a mask to specify which value to return.

These three methods are now explained in more detail using the following 3-by-3 matrix \( M \) as an example:

```matlab
>> M = magic(3)

ans =
     8     1     6
     3     5     7
     4     9     2
```

**Subscript indexing**

The most straightforward method for accessing an element, is to specify its row-column index. For example, accessing the element on the second row and third column:

```matlab
>> M(2, 3)

ans =
     7
```

The number of subscripts provided exactly matches the number of dimensions \( M \) has (two in this example).

Note that the order of subscripts is the same as the mathematical convention: row index is the first. Moreover, MATLAB indices **starts with 1 and not 0** like most programming languages.

You can index multiple elements at once by passing a vector for each coordinate instead of a single number. For example to get the entire second row, we can specify that we want the first, second and third columns:

```matlab
>> M(2, [1,2,3])

ans =
     3     5     7
```
In MATLAB, the vector \([1, 2, 3]\) is more easily created using the colon operator, i.e. \(1:3\). You can use this in indexing as well. To select an entire row (or column), MATLAB provides a shortcut by allowing you just specify \(::\). For example, the following code will also return the entire second row:

```matlab
>> M(2, :)
ans =
 3     5     7
```

MATLAB also provides a shortcut for specifying the last element of a dimension in the form of the `end` keyword. The `end` keyword will work exactly as if it was the number of the last element in that dimension. So if you want all the columns from column \(2\) to the last column, you can use write the following:

```matlab
>> M(2, 2:end)
ans =
 5     7
```

Subscript indexing can be restrictive as it will not allow to extract single values from different columns and rows; it will extract the combination of all rows and columns.

```matlab
>> M([2,3], [1,3])
ans =
  3     7
  4     2
```

For example subscript indexing cannot extract only the elements \(M(2,1)\) or \(M(3,3)\). To do this we must consider linear indexing.

**Linear indexing**

MATLAB allows you to treat n-dimensional arrays as one-dimensional arrays when you index using only one dimension. You can directly access the first element:

```matlab
>> M(1)
ans =
  8
```

Note that arrays are stored in **column-major order** in MATLAB which means that you access the elements by first going down the columns. So \(M(2)\) is the second element of the first column which is \(3\) and \(M(4)\) will be the first element of the second column i.e.

```matlab
>> M(4)
ans =
```
There exist built-in functions in MATLAB to convert subscript indices to linear indices, and vice versa: `sub2ind` and `ind2sub` respectively. You can manually convert the subscripts \((r,c)\) to a linear index by

\[
idx = r + (c-1) \times \text{size}(M, 1)
\]

To understand this, if we are in the first column then the linear index will simply be the row index. The formula above holds true for this because for \(c = 1\), \((c-1) = 0\). In the next columns, the linear index is the row number plus all the rows of the previous columns.

Note that the `end` keyword still applies and now refers to the very last element of the array i.e. \(M(\text{end}) = M(\text{end, end}) = 2\).

You can also index multiple elements using linear indexing. Note that if you do that, the returned matrix will have the same shape as the matrix of index vectors.

\(M(2:4)\) returns a row vector because \(2:4\) represents the row vector \([2, 3, 4]\):

```matlab
>> M(2:4)
ans =
    3    4    1
```

As an other example, \(M([1, 2; 3, 4])\) returns a 2-by-2 matrix because \([1, 2; 3, 4]\) is a 2-by-2 matrix as well. See the below code to convince yourself:

```matlab
>> M([1, 2; 3, 4])
ans =
    8    3
    4    1
```

Note that indexing with \(:\) alone will always return a column vector:

```matlab
>> M(:)
ans =
    8
    3
    4
    1
    5
    6
    7
    2
```
This example also illustrates the order in which MATLAB returns elements when using linear indexing.

**Logical indexing**

The third method of indexing is to use a logical matrix, i.e. a matrix containing only `true` or `false` values, as a mask to filter out the elements you don't want. For example, if we want to find all the elements of \( M \) that are greater than 5 we can use the logical matrix

\[
>> M > 5
\]

\[
\text{ans} = \\
1 \ 0 \ 1 \\
0 \ 0 \ 1 \\
0 \ 1 \ 0
\]

to index \( M \) and return only the values that are greater than 5 as follows:

\[
>> M(M > 5)
\]

\[
\text{ans} = \\
8 9 6 7
\]

If you wanted these number to stay in place (i.e. keep the shape of the matrix), then you could assign to the logic compliment

\[
>> M(~(M > 5)) = \text{NaN}
\]

\[
\text{ans} = \\
8 \ \text{NaN} \ 6 \\
\text{NaN} \ \text{NaN} \ 7 \\
\text{NaN} \ 9 \ \text{NaN}
\]

We can reduce complicated code blocks containing `if` and `for` statements by using logical indexing.

Take the non-vectorized (already shortened to a single loop by using linear indexing):

```matlab
for elem = 1:numel(M)
    if M(elem) > 5
        M(elem) = M(elem) - 2;
    end
end
```

This can be shortened to the following code using logical indexing:

```matlab
for elem = 1:numel(M)
    if M(elem) > 5
        M(elem) = M(elem) - 2;
    end
end
```
idx = M > 5;
M(idx) = M(idx) - 2;

Or even shorter:

\[ M(M > 5) = M(M > 5) - 2; \]

**More on indexing**

**Higher dimension matrices**

All the methods mentioned above generalize into n-dimensions. If we use the three-dimensional matrix \( M3 = \text{rand}(3,3,3) \) as an example, then you can access all the rows and columns of the second slice of the third dimension by writing

\[
\text{>> M(:,:,2)}
\]

You can access the first element of the second slice using linear indexing. Linear indexing will only move on to the second slice after all the rows and all the columns of the first slice. So the linear index for that element is

\[
\text{>> M(size(M,1)*size(M,2)+1)}
\]

In fact, in MATLAB, *every* matrix is n-dimensional: it just happens to be that the size of most of the other n-dimensions are one. So, if \( a = 2 \) then \( a(1) == 2 \) (as one would expect), but also \( a(1, 1) == 2 \), as does \( a(1, 1, 1) == 2, a(1, 1, 1, ..., 1) == 2 \) and so on. These "extra" dimensions (of size 1), are referred to as *singleton dimensions*. The command `squeeze` will remove them, and one can use `permute` to swap the order of dimensions around (and introduce singleton dimensions if required).

An n-dimensional matrix can also be indexed using an m subscripts (where \( m \leq n \)). The rule is that the first \( m-1 \) subscripts behave ordinarily, while the last (m'th) subscript references the remaining \( (n-m+1) \) dimensions, just as a linear index would reference an \( (n-m+1) \) dimensional array. Here is an example:

\[
\text{>> M = reshape(1:24, [2,3,4]);}
\]

\[
\text{\text{>> M(1,1)}}
\]

\[
\text{ans =}
\]

\[
\text{1}
\]

\[
\text{\text{>> M(1,10)}}
\]

\[
\text{ans =}
\]

\[
\text{19}
\]

\[
\text{\text{>> M(:,,:)}}
\]

\[
\text{ans =}
\]

\[
1  3  5  7  9 11 13 15 17 19 21 23 \\
2  4  6  8 10 12 14 16 18 20 22 24
\]

**Returning ranges of elements**
With subscript indexing, if you specify more than one element in more than one dimension, MATLAB returns each possible pair of coordinates. For example, if you try \( M([1,2],[1,3]) \) MATLAB will return \( M(1,1) \) and \( M(2,3) \) but it will also return \( M(1,3) \) and \( M(2,1) \). This can seem unintuitive when you are looking for the elements for a list of coordinate pairs but consider the example of a larger matrix, \( A = \text{rand}(20) \) (note \( A \) is now 20-by-20), where you want to get the top right hand quadrant. In this case instead of having to specify every coordinate pair in that quadrant (and this this case that would be 100 pairs), you just specify the 10 rows and the 10 columns you want so \( A(1:10, 11:end) \). *Slicing* a matrix like this is far more common than requiring a list of coordinate pairs.

In the event that you do want to get a list of coordinate pairs, the simplest solution is to convert to linear indexing. Consider the problem where you have a vector of column indices you want returned, where each row of the vector contains the column number you want returned for the corresponding row of the matrix. For example

```matlab
colIdx = [3;2;1]
```

So in this case you actually want to get back the elements at \((1,3)\), \((2,2)\) and \((3,1)\). So using linear indexing:

```matlab
>> colIdx = [3;2;1];
>> rowIdx = 1:length(colIdx);
>> idx = sub2ind(size(M), rowIdx, colIdx);
>> M(idx)
ans =
   6    5    4
```

**Returning an element multiple times**

With subscript and linear indexing you can also return an element multiple times by repeating it's index so

```matlab
>> M([1,1,1,2,2,2])
ans =
   8    8    8    3    3    3
```

You can use this to duplicate entire rows and column for example to repeat the first row and last column

```matlab
>> M([1, 1:end], [1:end, end])
ans =
   8    1    6    6
   8    1    6    6
   3    5    7    7
   4    9    2    2
```
Helping yourself

MATLAB comes with many built-in scripts and functions which range from simple multiplication to image recognition toolboxes. In order to get information about a function you want to use type: help functionname in the command line. Let's take the help function as an example.

Information on how to use it can be obtained by typing:

```matlab
>> help help
```

in the command window. This will return information of the usage of function help. If the information you are looking for is still unclear you can try the documentation page of the function. Simply type:

```matlab
>> doc help
```

in the command window. This will open the browsable documentation on the page for function help providing all the information you need to understand how the 'help' works.

This procedure works for all built-in functions and symbols.

When developing your own functions you can let them have their own help section by adding comments at the top of the function file or just after the function declaration.

Example for a simple function multiplyby2 saved in file multiplyby2.m

```matlab
function [prod]=multiplyby2(num)
% function MULTIPLYBY2 accepts a numeric matrix NUM and returns output PROD
% such that all numbers are multiplied by 2
    prod=num*2;
end
```

or

```matlab
% function MULTIPLYBY2 accepts a numeric matrix NUM and returns output PROD
% such that all numbers are multiplied by 2
function [prod]=multiplyby2(num)
    prod=num*2;
end
```

This is very useful when you pick up your code weeks/months/years after having written it.

The help and doc function provide a lot of information, learning how to use those features will help you progress rapidly and use MATLAB efficiently.

Reading Input & Writing Output

Just like all programming language, Matlab is designed to read and write in a large variety of
formats. The native library supports a large number of Text,Image,Video,Audio,Data formats with more formats included in each version update - check here to see the full list of supported file formats and what function to use to import them.

Before you attempt to load in your file, you must ask yourself what do you want the data to become and how you expect the computer to organize the data for you. Say you have a txt/csv file in the following format:

<table>
<thead>
<tr>
<th>Fruit</th>
<th>TotalUnits</th>
<th>UnitsLeftAfterSale</th>
<th>SellingPricePerUnit</th>
</tr>
</thead>
<tbody>
<tr>
<td>Apples</td>
<td>200</td>
<td>67</td>
<td>$0.14</td>
</tr>
<tr>
<td>Bananas</td>
<td>300</td>
<td>172</td>
<td>$0.11</td>
</tr>
<tr>
<td>Pineapple</td>
<td>500</td>
<td>12</td>
<td>$1.74</td>
</tr>
</tbody>
</table>

We can see that the first column is in the format of Strings, while the second, third are Numeric, the last column is in the form of Currency. Let's say we want to find how much revenue we made today using Matlab and first we want to load in this txt/csv file. After checking the link, we can see that String and Numeric type of txt files are handled by `textscan`. So we could try:

```matlab
g code text
fileID = fopen('dir/test.txt'); %Load file from dir
C = textscan(fileID,'%s %f %f %s','Delimiter',',','HeaderLines',1); %Parse in the txt/csv
```

where `%s` suggest that the element is a String type, `%f` suggest that the element is a Float type, and that the file is Delimited by ",". The `HeaderLines` option asks Matlab to skip the First N lines while the 1 immediately after it means to skip the first line (the header line).

Now C is the data we have loaded which is in the form of a Cell Array of 4 cells, each containing the column of data in the txt/csv file.

So first we want to calculate how many fruits we sold today by subtracting the third column from the second column, this can be done by:

```matlab
g code text
sold = C{2} - C{3}; %C{2} gives the elements inside the second cell (or the second column)
```

Now we want to multiply this vector by the Price per unit, so first we need to convert that column of Strings into a column of Numbers, then convert it into a Numeric Matrix using Matlab's `cell2mat` the first thing we need to do is to strip-off the "$" sign, there are many ways to do this. The most direct way is using a simple regex:

```matlab
g code text
D = cellfun(@(x)(str2num(regexprep(x, '\$', ''))), C{4}, 'UniformOutput', false); %cellfun allows us to avoid looping through each element in the cell.
```

Or you can use a loop:

```matlab
g code text
for t=1:size(C{4},1)
    D{t} = str2num(regexprep(C{4}{t}, '\$', ''));
end
E = cell2mat(D) % converts the cell array into a Matrix
```
The `str2num` function turns the string which had "$" signs stripped into numeric types and `cell2mat` turns the cell of numeric elements into a matrix of numbers.

Now we can multiply the units sold by the cost per unit:

```matlab
revenue = sold .* E; % element-wise product is denoted by .* in Matlab
totalrevenue = sum(revenue);
```

### Cell Arrays

Elements of the same class can often be concatenated into arrays (with a few rare exceptions, e.g. function handles). Numeric scalars, by default of class `double`, can be stored in a matrix.

```matlab
>> A = [1, -2, 3.14, 4/5, 5^6; pi, inf, 7/0, nan, log(0)]
A =
    1.0e+04 *
   0.0001   -0.0002    0.0003    0.0001    1.5625
   0.0003     Inf     Inf    NaN   -Inf
```

Characters, which are of class `char` in MATLAB, can also be stored in arrays using similar syntax. Such an array is similar to a string in many other programming languages.

```matlab
>> s = ['MATLAB ','is ','fun']
s =
    MATLAB is fun
```

Note that despite both of them are using brackets `[` and `]`, the result classes are different. Therefore the operations that can be done on them are also different.

```matlab
>> whos
Name      Size            Bytes  Class     Attributes
A         2x5                80  double
s         1x13               26  char
```

In fact, the array `s` is not an array of the strings `'MATLAB '`, `'is '`, and `'fun'`, it is just one string - an array of 13 characters. You would get the same results if it were defined by any of the following:

```matlab
>> s = ['MAT','LAB ','is f','u','n'];
>> s = ['M','A','T','L','A','B',' ','i','s',' ','f','u','n'];
```

A regular MATLAB vector does not let you store a mix of variables of different classes, or a few different strings. This is where the `cell` array comes in handy. This is an array of cells that each can contain some MATLAB object, whose class can be different in every cell if needed. Use curly braces `{` and `}` around the elements to store in a cell array.

```matlab
>> C = {A; s}
C =
    [2x5 double]
```
Standard MATLAB objects of any classes can be stored together in a cell array. Note that cell arrays require more memory to store their contents.

Accessing the contents of a cell is done using curly braces { and }.

Note that \texttt{C(1)} is different from \texttt{C{1}}. Whereas the latter returns the cell's content (and has class \texttt{double} in our example), the former returns a cell array which is a sub-array of \texttt{C}. Similarly, if \texttt{D} were an 10 by 5 cell array, then \texttt{D(4:8,1:3)} would return a sub-array of \texttt{D} whose size is 5 by 3 and whose class is \texttt{cell}. And the syntax \texttt{C{1:2}} does not have a single returned object, but rather it returns 2 different objects (similar to a MATLAB function with multiple return values):

\begin{verbatim}
>> [x,y] = C{1:2}

x =
  1.0000e+04 * 
    0.0010    -0.0002    0.0003    0.0001    1.5625
    0.0003        Inf        Inf       NaN      -Inf

y =
MATLAB is fun
\end{verbatim}

**Scripts and Functions**

MATLAB code can be saved in m-files to be reused. m-files have the \texttt{.m} extension which is automatically associated with MATLAB. An m-file can contain either a script or functions.

**Scripts**

Scripts are simply program files that execute a series of MATLAB commands in a predefined order.

Scripts do not accept input, nor do scripts return output. Functionally, scripts are equivalent to typing commands directly into the MATLAB command window and being able to replay them.

An example of a script:

```matlab
length = 10;
width = 3;
area = length * width;
```

https://riptutorial.com/
This script will define length, width, and area in the current workspace with the value 10, 3, and 30 respectively.

As stated before, the above script is functionally equivalent to typing the same commands directly into the command window.

```matlab
>> length = 10;
>> width = 3;
>> area = length * width;
```

## Functions

Functions, when compared to scripts, are much more flexible and extensible. Unlike scripts, functions can accept input and return output to the caller. A function has its own workspace, this means that internal operations of the functions will not change the variables from the caller.

All functions are defined with the same header format:

```matlab
function [output] = myFunctionName(input)
```

The `function` keyword begins every function header. The list of outputs follows. The list of outputs can also be a comma separated list of variables to return.

```matlab
function [a, b, c] = myFunctionName(input)
```

Next is the name of the function that will be used for calling. This is generally the same name as the filename. For example, we would save this function as `myFunctionName.m`.

Following the function name is the list of inputs. Like the outputs, this can also be a comma separated list.

```matlab
function [a, b, c] = myFunctionName(x, y, z)
```

We can rewrite the example script from before as a reusable function like the following:

```matlab
function [area] = calcRecArea(length, width)
    area = length * width;
end
```

We can call functions from other functions, or even from script files. Here is an example of our above function being used in a script file.

```matlab
l = 100;
w = 20;
a = calcRecArea(l, w);
```

As before, we create `l`, `w`, and `a` in the workspace with the values of 100, 20, and 2000 respectively.

## Data Types

https://riptutorial.com/
There are 16 fundamental data types, or classes, in MATLAB. Each of these classes is in the form of a matrix or array. With the exception of function handles, this matrix or array is a minimum of 0-by-0 in size and can grow to an n-dimensional array of any size. A function handle is always scalar (1-by-1).

Important moment in MATLAB is that you don't need to use any type declaration or dimension statements by default. When you define new variable MATLAB creates it automatically and allocates appropriate memory space.

Example:

```matlab
a = 123;
b = [1 2 3];
c = '123';
```

```
>> whos
Name      Size            Bytes  Class     Attributes
a         1x1                 8  double
b         1x3                24  double
  c         1x3                 6  char
```

If the variable already exists, MATLAB replaces the original data with new one and allocates new storage space if necessary.

**Fundamental data types**

Fundamental data types are: numeric, logical, char, cell, struct, table and function_handle.

**Numeric data types:**

- **Floating-Point numbers** *(default)*

  MATLAB represents floating-point numbers in either double-precision or single-precision format. The default is double precision, but you can make any number single precision with a simple conversion function:

  ```matlab
  a = 1.23;
b = single(a);
  ```

  ```
  >> whos
  Name      Size            Bytes  Class     Attributes
  a         1x1                 8  double
  b         1x1                 4  single
  ```

- **Integers**

  MATLAB has four signed and four unsigned integer classes. Signed types enable you to work with negative integers as well as positive, but cannot represent as wide a range of numbers as the unsigned types because one bit is used to designate a positive or negative sign for the number. Unsigned types give you a wider range of numbers, but these numbers
can only be zero or positive.

MATLAB supports 1-, 2-, 4-, and 8-byte storage for integer data. You can save memory and execution time for your programs if you use the smallest integer type that accommodates your data. For example, you do not need a 32-bit integer to store the value 100.

```matlab
a = int32(100);
b = int8(100);
```

```
>> whos
Name     Size    Bytes  Class  Attributes
a         1x1     4  int32
b         1x1     1  int8
```

To store data as an integer, you need to convert from double to the desired integer type. If the number being converted to an integer has a fractional part, MATLAB rounds to the nearest integer. If the fractional part is exactly 0.5, then from the two equally nearby integers, MATLAB chooses the one for which the absolute value is larger in magnitude.

```matlab
a = int16(456);
```

- char

Character arrays provide storage for text data in MATLAB. In keeping with traditional programming terminology, an array (sequence) of characters is defined as a string. There is no explicit string type in retail releases of MATLAB.

- logical: logical values of 1 or 0, represent true and false respectively. Use for relational conditions and array indexing. Because it’s just TRUE or FALSE it has size of 1 byte.

```matlab
a = logical(1);
```

- structure. A structure array is a data type that groups variables of different data types using data containers called fields. Each field can contain any type of data. Access data in a structure using dot notation of the form structName.fieldName.

```matlab
field1 = 'first';
field2 = 'second';
value1 = [1 2 3 4 5];
value2 = 'sometext';
s = struct(field1,value1,field2,value2);
```

In order to access value1, each of the following syntax are equivalent

```matlab
s.first or s.(field1) or s.'first'
```

We can explicitly access a field we know will exist with the first method, or either pass a string or create a string to access the field in the second example. The third example is demonstrating that the dot parenthases notation takes a string, which is the same one stored
in the field1 variable.

- table variables can be of different sizes and data types, but all variables must have the same number of rows.

```matlab
Age = [15 25 54]';
Height = [176 190 165]';
Name = {'Mike', 'Pete', 'Steeve'}';
T = table(Name, Age, Height);
```

- cell. It's very useful MATLAB data type: cell array is an array each element of it can be of different data type and size. It's very strong instrument for manipulating data as you wish.

```matlab
a = { [1 2 3], 56, 'art'};
```

or

```matlab
a = cell(3);
```

- function handles stores a pointer to a function (for example, to anonymous function). It allows you to pass a function to another function, or call local functions from outside the main function.

There are a lot of instruments to work with each data type and also built-in data type conversion functions (`str2double`, `table2cell`).

**Additional data types**

There are several additional data types which are useful in some specific cases. They are:

- Date and time: arrays to represent dates, time, and duration. `datetime('now')` returns 21-Jul-2016 16:30:16.

- Categorical arrays: it's data type for storing data with values from a set of discrete categories. Useful for storing nonnumeric data (memory effective). Can be used in a table to select groups of rows.

```matlab
a = categorical({'a' 'b' 'c'});
```

- Map containers is a data structure that has unique ability to indexing not only through the any scalar numeric values but character vector. Indices into the elements of a Map are called keys. These keys, along with the data values associated with them, are stored within the Map.

- Time series are data vectors sampled over time, in order, often at regular intervals. It's useful to store the data connected with timesteps and it has a lot of useful methods to work with.

**Anonymous functions and function handles**

https://riptutorial.com/
**Basics**

Anonymous functions are a powerful tool of the MATLAB language. They are functions that exist locally, that is: in the current workspace. However, they do not exist on the MATLAB path like a regular function would, e.g. in an m-file. That is why they are called anonymous, although they can have a name like a variable in the workspace.

**The `@` operator**

Use the `@` operator to create anonymous functions and function handles. For example, to create a handle to the `sin` function (sine) and use it as `f`:

\[
\text{>> } f = @\sin
\]

\[
f = \@\sin
\]

Now `f` is a handle to the `sin` function. Just like (in real life) a door handle is a way to use a door, a function handle is a way to use a function. To use `f`, arguments are passed to it as if it were the `sin` function:

\[
\text{>> } f(\pi/2)
\]

\[
\text{ans} = 1
\]

`f` accepts any input arguments the `sin` function accepts. If `sin` would be a function that accepts zero input arguments (which it does not, but others do, e.g. the `peaks` function), `f()` would be used to call it without input arguments.

**Custom anonymous functions**

**Anonymous functions of one variable**

It is not obviously useful to create a handle to an existing function, like `sin` in the example above. It is kind of redundant in that example. However, it is useful to create anonymous functions that do custom things that otherwise would need to be repeated multiple times or created a separate function for. As an example of a custom anonymous function that accepts one variable as its input, sum the sine and cosine squared of a signal:

\[
\text{>> } f = @(x) \sin(x)+\cos(x).^2
\]

\[
f = \@ (x) \sin(x)+\cos(x).^2
\]

Now `f` accepts one input argument called `x`. This was specified using parentheses `(..)` directly after the `@` operator. `f` now is an anonymous function of `x`: `f(x)`. It is used by passing a value of `x` to `f`:
A vector of values or a variable can also be passed to \( f \), as long as they are used in a valid way within \( f \):

```matlab
>> f(1:3) % pass a vector to f
ans =
     1.1334    1.0825    1.1212
>> n = 5:7;
>> f(n) % pass n to f
ans =
    -0.8785    0.6425    1.2254
```

Anonymous functions of more than one variable

In the same fashion anonymous functions can be created to accept more than one variable. An example of an anonymous function that accepts three variables:

```matlab
>> f = @(x,y,z) x.^2 + y.^2 - z.^2
f =
    @(x,y,z)x.^2+y.^2-z.^2
>> f(2,3,4)
ans =
    -3
```

Parameterizing anonymous functions

Variables in the workspace can be used within the definition of anonymous functions. This is called parameterizing. For example, to use a constant \( c = 2 \) in an anonymous function:

```matlab
>> c = 2;
>> f = @(x) c*x
f =
    @(x)c*x
>> f(3)
ans =
    6
```

\( f(3) \) used the variable \( c \) as a parameter to multiply with the provided \( x \). Note that if the value of \( c \) is set to something different at this point, then \( f(3) \) is called, the result would not be different. The value of \( c \) is the value at the time of creation of the anonymous function:

```matlab
>> c = 2;
>> f = @(x) c*x;
>> f(3)
ans =
    6
>> c = 3;
>> f(3)
ans =
```

https://riptutorial.com/
Input arguments to an anonymous function do not refer to workspace variables

Note that using the name of variables in the workspace as one of the input arguments of an anonymous function (i.e., using \( @(...) \)) will not use those variables' values. Instead, they are treated as different variables within the scope of the anonymous function, that is: the anonymous function has its private workspace where the input variables never refer to the variables from the main workspace. The main workspace and the anonymous function's workspace do not know about each other's contents. An example to illustrate this:

\[
\begin{align*}
\text{>> } x &= 3 \% x \text{ in main workspace} \\
& \quad x = 3 \\
\text{>> } f &= @(x) x+1; \% x \text{ refers to a private } x \text{ variable} \\
& \quad f(5) \\
& \quad \text{ans} = 6 \\
\text{>> } x \\
& \quad x = 3
\end{align*}
\]

The value of \( x \) from the main workspace is not used within \( f \). Also, in the main workspace \( x \) was left untouched. Within the scope of \( f \), the variable names between parentheses after the \( @ \) operator are independent from the main workspace variables.

Anonymous functions are stored in variables

An anonymous function (or, more precisely, the function handle pointing at an anonymous function) is stored like any other value in the current workspace: In a variable (as we did above), in a cell array \( \{ @ (x) x.^2, @(x)x+1 \} \), or even in a property (like \( h.ButtonDownFcn \) for interactive graphics). This means the anonymous function can be treated like any other value. When storing it in a variable, it has a name in the current workspace and can be changed and cleared just like variables holding numbers.

Put differently: A function handle (whether in the \( @sin \) form or for an anonymous function) is simply a value that can be stored in a variable, just like a numerical matrix can be.

Advanced use

Passing function handles to other functions

Since function handles are treated like variables, they can be passed to functions that accept function handles as input arguments.

An example: A function is created in an m-file that accepts a function handle and a scalar number.
It then calls the function handle by passing \(3\) to it and then adds the scalar number to the result. The result is returned.

**Contents of `funHandleDemo.m`**:

```matlab
function y = funHandleDemo(fun,x)
    y = fun(3);
    y = y + x;
end
```

Save it somewhere on the path, e.g. in MATLAB’s current folder. Now `funHandleDemo` can be used as follows, for example:

```matlab
>> f = @(x) x^2;  % an anonymous function
>> y = funHandleDemo(f,10)  % pass f and a scalar to funHandleDemo
y =
  19
```

The handle of another existing function can be passed to `funHandleDemo`:

```matlab
>> y = funHandleDemo(@sin,-5)
y =
  -4.8589
```

Notice how `@sin` was a quick way to access the `sin` function without first storing it in a variable using `f = @sin`.

**Using `bsxfun`, `cellfun` and similar functions with anonymous functions**

MATLAB has some built-in functions that accept anonymous functions as an input. This is a way to perform many calculations with a minimal number of lines of code. For example `bsxfun`, which performs element-by-element binary operations, that is: it applies a function on two vectors or matrices in an element-by-element fashion. Normally, this would require use of `for`-loops, which often requires preallocation for speed. Using `bsxfun` this process is sped up. The following example illustrates this using `tic` and `toc`, two functions that can be used to time how long code takes. It calculates the difference of every matrix element from the matrix column mean.

```matlab
A = rand(50);  % 50-by-50 matrix of random values between 0 and 1

% method 1: slow and lots of lines of code
 tic
 meanA = mean(A);  % mean of every matrix column: a row vector
 result = zeros(size(A));
 for j = 1:size(A,1)
     result(j,:) = A(j,:) - meanA;
 end
 toc
 clear result % make sure method 2 creates its own result

% method 2: fast and only one line of code
```
tic
result = bsxfun(@minus,A,mean(A));
toc

Running the example above results in two outputs:

Elapsed time is 0.015153 seconds.
Elapsed time is 0.007884 seconds.

These lines come from the toc functions, which print the elapsed time since the last call to the tic function.

The bsxfun call applies the function in the first input argument to the other two input arguments. @minus is a long name for the same operation as the minus sign would do. A different anonymous function or handle (@) to any other function could have been specified, as long as it accepts A and mean(A) as inputs to generate a meaningful result.

Especially for large amounts of data in large matrices, bsxfun can speed up things a lot. It also makes code look cleaner, although it might be more difficult to interpret for people who don’t know MATLAB or bsxfun. (Note that in MATLAB R2016a and later, many operations that previously used bsxfun no longer need them; A-mean(A) works directly and can in some cases be even faster.)

Read Getting started with MATLAB Language online:
Chapter 2: Common mistakes and errors

Examples

Do not name a variable with an existing function name

There is already a function sum(). As a result, if we name a variable with the same name

\[
\text{sum} = 1+3;
\]

and if we try to use the function while the variable still exists in the workspace

\[
\text{A} = \text{rand}(2);
\]
\[
\text{sum(A,1)}
\]

we will get the cryptic error:

Subscript indices must either be real positive integers or logicals.

\text{clear()} \text{ the variable first and then use the function}

\[
\text{clear sum}
\]
\[
\text{sum(A,1)}
\]
\[
\text{ans} =
\]
\[
1.0826 \quad 1.0279
\]

How can we check if a function already exists to avoid this conflict?

Use \text{which()} with the \text{-all} flag:

\[
\text{which sum -all}
\]

\[
\text{sum is a variable.}
\]
\[
\text{built-in (C:\Program Files\MATLAB\R2016a\toolbox\matlab\datafun}@double\sum) \quad \% \text{Shadowed double method}
\]
\[
\ldots
\]

This output is telling us that \text{sum} is first a variable and that the following methods (functions) are shadowed by it, i.e. MATLAB will first try to apply our syntax to the variable, rather than using the method.

What you see is NOT what you get: char vs cellstring in the command window

This a basic example aimed at new users. It does not focus on explaining the difference between char and cellstring.

https://riptutorial.com/
It might happen that you want to get rid of the ' in your strings, although you never added them. In fact, those are artifacts that the command window uses to distinguish between some types.

A **string** will print

```matlab
s = 'dsadasd'
s =
dsadasd
```

A **cellstring** will print

```matlab
c = {'dsadasd'};
c =
'dsadasd'
```

Note how the **single quotes** and the **indentation** are artifacts to notify us that `c` is a **cellstring** rather than a **char**. The string is in fact contained in the cell, i.e.

```matlab
c(1)
ans =
dsadasd
```

The transpose operators

- '. ' is the correct way to **transpose** a vector or matrix in MATLAB.
- '. ' is the correct way to take the **complex conjugate transpose** (a.k.a. Hermitian conjugate) of a vector or matrix in MATLAB.

Note that for the transpose '. ', there is a **period** in front of the apostrophe. This is in keeping with the syntax for the other element-wise operations in MATLAB: · multiplies **matrices**, . · multiplies **elements of matrices** together. The two commands are very similar, but conceptually very distinct. Like other MATLAB commands, these operators are "syntactical sugar" that gets turned into a "proper" function call at runtime. Just as -- becomes an evaluation of the `eq` function, think of . ' as the shorthand for `transpose`. If you would only write ' (without the point), you are in fact using the `ctranspose` command instead, which calculates the **complex conjugate transpose**, which is also known as the **Hermitian conjugate**, often used in physics. As long as the transposed vector or matrix is real-valued, the two operators produce the same result. But as soon as we deal with **complex numbers**, we will inevitably run into problems if we do not use the "correct" shorthand. What "correct" is depends on your application.

Consider the following example of a matrix `C` containing complex numbers:

```matlab
>> C = [1i, 2; 3*1i, 4]
C =
0.0000 + 1.0000i  2.0000 + 0.0000i
0.0000 + 3.0000i  4.0000 + 0.0000i
```

Let's take the **transpose** using the shorthand . '. (with the period). The output is as expected, the transposed form of `C`.  

https://riptutorial.com/
Now, let's use \( \cdot \) (without the period). We see, that in addition to the transposition, the complex values have been transformed to their complex conjugates as well.

To sum up, if you intend to calculate the Hermitian conjugate, the complex conjugate transpose, then use \( \cdot \) (without the period). If you just want to calculate the transpose without complex-conjugating the values, use \( .\) (with the period).

**Undefined Function or Method X for Input Arguments of Type Y**

This is MATLAB's long-winded way of saying that it cannot find the function that you're trying to call. There are a number of reasons you could get this error:

---

**That function was introduced *after* your current version of MATLAB**

The MATLAB online documentation provides a very nice feature which allows you to determine in what version a given function was introduced. It is located in the bottom left of every page of the documentation:

**More About**

- Tips
  - The behavior of \texttt{histcounts} is similar to that of the \texttt{discretize} function which bin each element belongs to (without counting).
  - Replace Discouraged Instances of \texttt{hist} and \texttt{histc}

**See Also**

\texttt{discretize|histcounts2|histogram|histogram2}

---

Compare this version with your own current version (\texttt{ver}) to determine if this function is available in your particular version. If it's not, try searching the archived versions of the documentation to find a suitable alternative in your version.
You don't have that toolbox!

The base MATLAB installation has a large number of functions; however, more specialized functionality is packaged within toolboxes and sold separately by the Mathworks. The documentation for all toolboxes is visible whether you have the toolbox or not so be sure to check and see if you have the appropriate toolbox.

To check which toolbox a given function belongs to, look to the top left of the online documentation to see if a specific toolbox is mentioned.

You can then determine which toolboxes your version of MATLAB has installed by issuing the `ver` command which will print a list of all installed toolboxes.

If you do not have that toolbox installed and want to use the function, you will need to purchase a license for that particular toolbox from The Mathworks.

MATLAB cannot locate the function

If MATLAB still can't find your function, then it must be a user-defined function. It is possible that it lives in another directory and that directory should be added to the search path for your code to run. You can check whether MATLAB can locate your function by using `which` which should return the path to the source file.

Be aware of floating point inaccuracy

Floating-point numbers cannot represent all real numbers. This is known as floating point inaccuracy.
There are infinitely many floating points numbers and they can be infinitely long (e.g. \( \pi \)), thus being able to represent them perfectly would require infinitely amount of memory. Seeing this was a problem, a special representation for "real number" storage in computer was designed, the \textbf{IEEE 754 standard}. In short, it describes how computers store this type of numbers, with an exponent and mantissa, as,

\[
\text{floatnum} = \text{sign} \times 2^\text{exponent} \times \text{mantissa}
\]

With limited amount of bits for each of these, only a finite precision can be achieved. The smaller the number, smaller the gap between possible numbers (and vice versa!). You can try your real numbers \textbf{in this online demo}.

Be aware of this behavior and try to avoid all floating points comparison and their use as stopping conditions in loops. See below two examples:

\textbf{Examples: Floating point comparison done WRONG:}

\begin{verbatim}
>> 0.1 + 0.1 + 0.1  == 0.3
ans =
   logical
   0
\end{verbatim}

It is poor practice to use floating point comparison as shown by the precedent example. You can overcome it by taking the absolute value of their difference and comparing it to a (small) tolerance level.

Below is another example, where a floating point number is used as a stopping condition in a while loop:**

\begin{verbatim}
k = 0.1;
while k <= 0.3
   disp(num2str(k));
   k = k + 0.1;
end
% --- Output: ---
0.1
0.2
\end{verbatim}

It misses the last expected loop \((0.3 <= 0.3)\).

\textbf{Example: Floating point comparison done RIGHT:}

\begin{verbatim}
x = 0.1 + 0.1 + 0.1;
y = 0.3;
tolerance = 1e-10; % A "good enough" tolerance for this case.
if ( abs( x - y ) <= tolerance )
   disp('x == y');
\end{verbatim}

https://riptutorial.com/
Several things to note:

- As expected, now $x$ and $y$ are treated as equivalent.
- In the example above, the choice of tolerance was done arbitrarily. Thus, the chosen value might not be suitable for all cases (especially when working with much smaller numbers). Choosing the bound *intelligently* can be done using the `eps` function, i.e. $N \cdot \text{eps}(\max(x,y))$, where $N$ is some problem-specific number. A reasonable choice for $N$, which is also permissive enough, is $1E2$ (even though, in the above problem $N=1$ would also suffice).

**Further reading:**

See these questions for more information about floating point inaccuracy:

- Why is 24.0000 not equal to 24.0000 in MATLAB?
- Is floating point math broken?

**Not enough input arguments**

Often beginning MATLAB developers will use MATLAB's editor to write and edit code, in particular custom functions with inputs and outputs. There is a *Run* button at the top that is available in recent versions of MATLAB:

Once the developer finishes with the code, they are often tempted to push the *Run* button. For some functions this will work fine, but for others they will receive a *Not enough input arguments* error and be puzzled about why the error occurs.

The reason why this error may not happen is because you wrote a MATLAB script or a function that takes in no input arguments. Using the *Run* button will run a test script or run a function assuming no input arguments. If your function requires input arguments, the *Not enough input arguments* error will occur as you have written a functions that expects inputs to go inside the function. Therefore, you cannot expect the function to run by simply pushing the *Run* button.

To demonstrate this issue, suppose we have a function `mult` that simply multiplies two matrices together:

```matlab
function [out] = mult(x, y)
%matrix multiplication
out = x * y;
end
```
function C = mult(A, B)
    C = A * B;
end

In recent versions of MATLAB, if you wrote this function and pushed the Run button, it will give you the error we expect:

```
>> mult
Not enough input arguments.
Error in mult (line 2)
    C = A * B;
```

There are two ways to resolve this issue:

**Method #1 - Through the Command Prompt**

Simply create the inputs you need in the Command Prompt, then run the function using those inputs you have created:

```
A = rand(5,5);
B = rand(5,5);
C = mult(A,B);
```

**Method #2 - Interactively through the Editor**

Underneath the Run button, there is a dark black arrow. If you click on that arrow, you can specify the variables you would like to get from the MATLAB workspace by typing the way you want to call the function exactly as how you have seen in method #1. Be sure that the variables you are specifying inside the function exist in the MATLAB workspace:

Watch out for array size changes

Some common operations in MATLAB, like **differentiation** or **integration**, output results that have a different amount of elements than the input data has. This fact can easily be overlooked, which would usually cause errors like `Matrix dimensions must agree`. Consider the following example:

```
t = 0:0.1:10;  % Declaring a time vector
```
\[ y = \sin(t); \quad \text{\% Declaring a function} \]
\[ dy_{dt} = \text{diff}(y); \quad \text{\% calculates dy/dt for } y = \sin(t) \]

Let's say we want to plot these results. We take a look at the array sizes and see:

\[
\begin{align*}
\text{size}(y) & \text{ is 1x101} \\
\text{size}(t) & \text{ is 1x101} \\
\end{align*}
\]

But:

\[
\text{size}(dy_{dt}) \text{ is 1x100}
\]

The array is one element shorter!

Now imagine you have measurement data of positions over time and want to calculate \( \text{ jerk}(t) \), you will get an array 3 elements less than the time array (because the jerk is the position differentiated 3 times).

\[
\begin{align*}
\text{vel} & = \text{diff}(y); \quad \text{\% calculates velocity vel=dy/dt for } y = \sin(t) \quad \text{size(vel)=1x100} \\
\text{acc} & = \text{diff(vel)}; \quad \text{\% calculates acceleration acc=d(vel)/dt} \quad \text{size(acc)=1x99} \\
\text{jerk} & = \text{diff(acc)}; \quad \text{\% calculates jerk jerk=d(acc)/dt} \quad \text{size(jerk)=1x98} \\
\end{align*}
\]

And then operations like:

\[
\text{x} = \text{jerk} \ast t; \quad \% \text{multiplies jerk and t element wise}
\]

return errors, because the matrix dimensions do not agree.

To calculate operations like above you have to adjust the bigger array size to fit the smaller one. You could also run a regression (\text{polyfit}) with your data to get a polynomial for your data.

**Dimension Mismatch Errors**

**Dimension mismatch** errors typically appear when:

- Not paying attention to the shape of returned variables from function/method calls. In many inbuilt MATLAB functions, matrices are converted into vectors to speed up the calculations, and the returned variable might still be a vector rather than the matrix we expected. This is also a common scenario when \text{logical masking} is involved.
- Using incompatible array sizes while invoking \text{implicit array expansion}.

The use of "i" or "j" as imaginary unit, loop indices or common variable.

**Recommendation**

Because the symbols \text{i} and \text{j} can represent significantly different things in MATLAB, their use as
loop indices has split the MATLAB user community since ages. While some historic performance reasons could help the balance lean to one side, this is no longer the case and now the choice rest entirely on you and the coding practices you choose to follow.

The current official recommendations from Mathworks are:

- Since \( i \) is a function, it can be overridden and used as a variable. However, it is best to avoid using \( i \) and \( j \) for variable names if you intend to use them in complex arithmetic.
- For speed and improved robustness in complex arithmetic, use \( \texttt{1i} \) and \( \texttt{1j} \) instead of \( i \) and \( j \).

Default

In MATLAB, by default, the letters \( i \) and \( j \) are built-in function names, which both refer to the imaginary unit in the complex domain.

So by default \( i = j = \text{sqrt}(-1) \).

```
>> i
ans =
  0.0000 + 1.0000i
>> j
ans =
  0.0000 + 1.0000i
```

and as you should expect:

```
>> i^2
ans =
  -1
```

Using them as a variable (for loop indices or other variable)

MATLAB allows using built-in function name as a standard variable. In this case the symbol used will not point to the built-in function any more but to your own user defined variable. This practice, however, is not generally recommended as it can lead to confusion, difficult debugging and maintenance (see other example do-not-name-a-variable-with-an-existing-function-name).

If you are ultra pedantic about respecting conventions and best practices, you will avoid using them as loop indices in this language. However, it is allowed by the compiler and perfectly functional so you may also choose to keep old habits and use them as loop iterators.

```
>> A = nan(2,3);
>> for i=1:2    % perfectly legal loop construction
    for j = 1:3
      A(i, j) = 10 * i + j;
```
Note that loop indices do not go out of scope at the end of the loop, so they keep their new value.

```matlab
>> [ i ; j ]
ans =
 2
 3
```

In the case you use them as variable, make sure they are initialised before they are used. In the loop above MATLAB initialise them automatically when it prepare the loop, but if not initialised properly you can quickly see that you may inadvertently introduce complex numbers in your result.

If later on, you need to undo the shadowing of the built-in function (=e.g. you want \( i \) and \( j \) to represent the imaginary unit again), you can clear the variables:

```matlab
>> clear i j
```

You understand now the Mathworks reservation about using them as loop indices if you intend to use them in complex arithmetic. Your code would be riddled with variable initialisations and clear commands, best way to confuse the most serious programmer (yes you there!...) and program accidents waiting to happen.

If no complex arithmetic is expected, the use of \( i \) and \( j \) is perfectly functional and there is no performance penalty.

### Using them as imaginary unit:

If your code has to deal with complex numbers, then \( i \) and \( j \) will certainly come in handy. However, for the sake of disambiguation and even for performances, it is recommended to use the full form instead of the shorthand syntax. The full form is \( 1i \) (or \( 1j \)).

```matlab
>> [ i ; j ; 1i ; 1j]
ans =
 0.0000 + 1.0000i
 0.0000 + 1.0000i
 0.0000 + 1.0000i
 0.0000 + 1.0000i
```

They do represent the same value \( \sqrt{-1} \), but the later form:

- is more explicit, in a semantic way.
- is more maintainable (someone looking at your code later will not have to read up the code to find whether \( i \) or \( j \) was a variable or the imaginary unit).
- is faster (source: Mathworks).

Note that the full syntax \( 1i \) is valid with any number preceding the symbol:

```matlab
https://riptutorial.com/ 34```
This is the only function which you can stick with a number without an operator between them.

**Pitfalls**

While their use as *imaginary unit* **OR** *variable* is perfectly legal, here is just a small example of how confusing it could get if both usages get mixed:

Let's override `i` and make it a variable:

```
>> i=3
i =
3
```

Now `i` is a *variable* (holding the value `3`), but we only overrid the *shorthand* notation of the imaginary unit, the full form is still interpreted correctly:

```
>> 3i
ans =
0.0000 + 3.0000i
```

Which now lets us build the most obscure formulations. I let you assess the readability of all the following constructs:

```
>> [ i ; 3i ; 3*i ; i+3i ; i+3*i ]
ans =
3.0000 + 0.0000i
0.0000 + 3.0000i
9.0000 + 0.0000i
3.0000 + 3.0000i
12.0000 + 0.0000i
```

As you can see, each value in the array above return a different result. While each result is valid (provided that was the initial intent), most of you will admit that it would be a proper nightmare to read a code riddled with such constructs.

**Using `length` for multidimensional arrays**

A common mistake MATLAB coders have, is using the `length` function for matrices (as opposed to *vectors*, for which it is intended). The `length` function, as mentioned in its documentation, "*returns the length of the largest array dimension*" of the input.

For vectors, the return value of `length` has two different meanings:

1. The total number of elements in the vector.
2. The largest dimension of the vector.
Unlike in vectors, the above values would not be equal for arrays of more than one non-singleton (i.e. whose size is larger than 1) dimension. This is why using `length` for matrices is ambiguous. Instead, using one of the following functions is encouraged, even when working with vectors, to make the intention of the code perfectly clear:

1. `size(A)` - returns a row vector whose elements contain the amount of elements along the corresponding dimension of `A`.
2. `numel(A)` - returns the number of elements in `A`. Equivalent to `prod(size(A))`.
3. `ndims(A)` - returns the number of dimensions in the array `A`. Equivalent to `numel(size(A))`.

This is especially important when writing "future-proof", vectorized library functions, whose inputs are not known in advance, and can have various sizes and shapes.

Read Common mistakes and errors online: https://riptutorial.com/matlab/topic/973/common-mistakes-and-errors
Chapter 3: Conditions

Syntax

- `if expression ... end`
- `if expression ... else ... end`
- `if expression ... elseif expression ... end`
- `if expression ... elseif expression ... else ... end`

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>expression</code></td>
<td>an expression that has logical meaning</td>
</tr>
</tbody>
</table>

Examples

IF condition

Conditions are a fundamental part of almost any part of code. They are used to execute some parts of the code only in some situations, but not other. Let's look at the basic syntax:

```plaintext
a = 5;
if a > 10    % this condition is not fulfilled, so nothing will happen
    disp('OK')
end

if a < 10    % this condition is fulfilled, so the statements between the if...end are executed
    disp('Not OK')
end
```

Output:

Not OK

In this example we see the `if` consists of 2 parts: the condition, and the code to run if the condition is true. The code is everything written after the condition and before the `end` of that `if`. The first condition was not fulfilled and hence the code within it was not executed.

Here is another example:

```plaintext
a = 5;
if a ~= a+1    % "~=" means "not equal to"
    disp('It''s true!') % we use two apostrophes to tell MATLAB that the ' is part of the string
```

https://riptutorial.com/
The condition above will always be true, and will display the output *It's true!*

We can also write:

```matlab
a = 5;
if a == a+1 % "==" means "is equal to", it is NOT the assignment ("=") operator
    disp('Equal')
end
```

This time the condition is always false, so we will never get the output *Equal*.

There is not much use for conditions that are always true or false, though, because if they are always false we can simply delete this part of the code, and if they are always true then the condition is not needed.

### IF-ELSE condition

In some cases we want to run an alternative code if the condition is false, for this we use the optional `else` part:

```matlab
a = 20;
if a < 10
    disp('a smaller than 10')
else
    disp('a bigger than 10')
end
```

Here we see that because `a` is not smaller than 10 the second part of the code, after the `else` is executed and we get the output *a bigger than 10*. Now let's look at another try:

```matlab
a = 10;
if a > 10
    disp('a bigger than 10')
else
    disp('a smaller than 10')
end
```

In this example shows that we did not checked if `a` is indeed smaller than 10, and we get a wrong message because the condition only check the expression as it is, and ANY case that does not equals true (`a = 10`) will cause the second part to be executed.

This type of error is a very common pitfall for both beginners and experienced programmers, especially when conditions become complex, and should be always kept in mind.

### IF-ELSEIF condition

Using `else` we can perform some task when the condition is not satisfied. But what if we want to check a second condition in case that the first one was false. We can do it this way:

```matlab
https://riptutorial.com/  38
a = 9;
if mod(a,2)==0  % MOD - modulo operation, return the remainder after division of 'a' by 2
    disp('a is even')
else
    if mod(a,3)==0
        disp('3 is a divisor of a')
    end
end
end
OUTPUT:
3 is a divisor of a

This is also called "nested condition", but here we have a special case that can improve code readability, and reduce the chance for an error - we can write:

a = 9;
if mod(a,2)==0
    disp('a is even')
else if mod(a,3)==0
    disp('3 is a divisor of a')
end
end
OUTPUT:
3 is a divisor of a

using the elseif we are able to check another expression within the same block of condition, and this is not limited to one try:

a = 25;
if mod(a,2)==0
    disp('a is even')
else if mod(a,3)==0
    disp('3 is a divisor of a')
else if mod(a,5)==0
    disp('5 is a divisor of a')
end
end
OUTPUT:
5 is a divisor of a

Extra care should be taken when choosing to use elseif in a row, since only one of them will be executed from all the if to end block. So, in our example if we want to display all the divisors of a (from those we explicitly check) the example above won't be good:

a = 15;
if mod(a,2)==0
    disp('a is even')
else if mod(a,3)==0
    disp('3 is a divisor of a')
else if mod(a,5)==0
    disp('5 is a divisor of a')
else if mod(a,15)==0
    disp('15 is a divisor of a')
end
end
OUTPUT:
3 is a divisor of a

https://riptutorial.com/
not only 3, but also 5 is a divisor of 15, but the part that check the division by 5 is not reached if any of the expressions above it was true.

Finally, we can add one else (and only one) after all the elseif conditions to execute a code when none of the conditions above are met:

```matlab
a = 11;
if mod(a,2)==0
    disp('a is even')
elseif mod(a,3)==0
    disp('3 is a divisor of a')
elseif mod(a,5)==0
    disp('5 is a divisor of a')
else
    disp('2, 3 and 5 are not divisors of a')
end
```

```
OUTPUT:
2, 3 and 5 are not divisors of a
```

**Nested conditions**

When we use a condition within another condition we say the conditions are "nested". One special case of nested conditions is given by the elseif option, but there are numerous other ways to use nested conditions. Let's examine the following code:

```matlab
a = 2;
if mod(a,2)==0    % MOD - modulo operation, return the remainder after division of 'a' by 2
    disp('a is even')
    if mod(a,3)==0
        disp('3 is a divisor of a')
        if mod(a,5)==0
            disp('5 is a divisor of a')
        end
    end
else
    disp('a is odd')
end
```

For `a=2`, the output will be a is even, which is correct. For `a=3`, the output will be a is odd, which is also correct, but misses the check if 3 is a divisor of a. This is because the conditions are nested, so only if the first is true, than we move to the inner one, and if a is odd, none of the inner conditions are even checked. This is somewhat opposite to the use of elseif where only if the first condition is false than we check the next one. What about checking the division by 5? only a number that has 6 as a divisor (both 2 and 3) will be checked for the division by 5, and we can test and see that for a=30 the output is:

```matlab
a = 30
if mod(a,2)==0
    disp('a is even')
    if mod(a,3)==0
        disp('3 is a divisor of a')
        if mod(a,5)==0
            disp('5 is a divisor of a')
        end
    end
else
    disp('a is odd')
end
```

We should also notice two things:

```
a is even
3 is a divisor of a
5 is a divisor of a
```
1. The position of the `end` in the right place for each `if` is crucial for the set of conditions to work as expected, so indentation is more than a good recommendation here.
2. The position of the `else` statement is also crucial, because we need to know in which `if` (and there could be several of them) we want to do something in case the expression `if false`.

Let's look at another example:

```matlab
for a = 5:10    % the FOR loop execute all the code within it for every a from 5 to 10
    ch = num2str(a);    % NUM2STR converts the integer a to a character
    if mod(a,2)==0
        if mod(a,3)==0
            disp(['3 is a divisor of ' ch])
        elseif mod(a,4)==0
            disp(['4 is a divisor of ' ch])
        else
            disp([ch ' is even'])
        end
    elseif mod(a,3)==0
        disp(['3 is a divisor of ' ch])
    else
        disp([ch ' is odd'])
    end
end
```

And the output will be:

```
5 is odd
3 is a divisor of 6
7 is odd
4 is a divisor of 8
3 is a divisor of 9
10 is even
```

we see that we got only 6 lines for 6 numbers, because the conditions are nested in a way that ensure only one print per number, and also (although can't be seen directly from the output) no extra checks are preformed, so if a number is not even there is no point to check if 4 is one of it divisors.

Read Conditions online: https://riptutorial.com/matlab/topic/3806/conditions
Chapter 4: Controlling Subplot coloring in Matlab

Introduction

As I was struggling with this more than once, and the web isn't really clear on what to do, I decided to take what's out there, adding some of my own in order to explain how to create subplots which have one colorbar and they are scaled according to it.

I have tested this using latest Matlab but I'm pretty sure it'll work in older versions.

Remarks

The only thing that you need to work out by yourself is the positioning of the colorbar (if you want to display it at all). this will depend on the number of graphs you have, and the bar's orientation.

Position and size is defined using 4 parameters - x_start, y_start, x_width, y_width. The plot is usually scaled to normalized units so that the bottom-left corner corresponds with (0,0) and the top-right to (1,1).

Examples

How it's done

This is a simple code creating 6 3d-subplots and in the end syncing the color displayed in each of them.

```matlab
c_fin = [0,0];
[X,Y] = meshgrid(1:0.1:10,1:0.1:10);
figure; hold on;
for i = 1 : 6
    Z(:,:,i) = i * (sin(X) + cos(Y));
    ax(i) = subplot(3,2,i); hold on; grid on;
    surf(X, Y, Z(:,:,i));
    view(-26,30);
    colormap('jet');
    ca = caxis;
    c_fin = [min(c_fin(1),ca(1)), max(c_fin(2),ca(2))];
end

%%you can stop here to see how it looks before we color-manipulate

c = colorbar('eastoutside');
c.Label.String = 'Units';
set(c, 'Position', [0.9, 0.11, 0.03, 0.815]); %you may want to play with these values
pause(2); %need this to allow the last image to resize itself before changing its axes
```

https://riptutorial.com/
for i = 1 : 6
    pos=get(ax(i), 'Position');
    axes(ax(i));
    set(ax(i), 'Position', [pos(1) pos(2) 0.85*pos(3) pos(4)]);
    set(ax(i), 'Clim', c_fin); % this is where the magic happens
end

Chapter 5: Debugging

Syntax

- `dbstop in file at location if expression`

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>file</td>
<td>Name of <code>.m</code> file (without extension), e.g. <code>fit</code>. This parameter is <em>(Required)</em> unless setting special conditional breakpoint types such as <code>dbstop if error</code> or <code>dbstop if naninf</code>.</td>
</tr>
<tr>
<td>location</td>
<td>Line number where the breakpoint should be placed. If the specified line does not contain runnable code, the breakpoint will be placed on the first valid line after the specified one.</td>
</tr>
<tr>
<td>expression</td>
<td>Any expression or combination thereof that evaluates to a boolean value. Examples: <code>ind == 1</code>, <code>nargin &lt; 4 &amp;&amp; isdir('Q:\')</code>.</td>
</tr>
</tbody>
</table>

Examples

Working with Breakpoints

Definition

*In software development, a **breakpoint** is an intentional stopping or pausing place in a program, put in place for debugging purposes.*

*More generally, a breakpoint is a means of acquiring knowledge about a program during its execution. During the interruption, the programmer inspects the test environment (general purpose registers, memory, logs, files, etc.) to find out whether the program is functioning as expected. In practice, a breakpoint consists of one or more conditions that determine when a program's execution should be interrupted.*

-Wikipedia

Breakpoints in MATLAB

Motivation
In MATLAB, when execution pauses at a breakpoint, variables existing in the current workspace (a.k.a. *scope*) or any of the calling workspaces, can be inspected (and usually also modified).

### Types of Breakpoints

MATLAB allow users to place two types of breakpoints in `.m` files:

- **Standard (or "unrestricted")** breakpoints (shown in red) - pause execution whenever the marked line is reached.
- "Conditional" breakpoints (shown in yellow) - pause execution whenever the marked line is reached AND the condition defined in the breakpoint is evaluated as `true`.

### Placing Breakpoints

Both types of breakpoints can be created in several ways:

- Using the MATLAB Editor GUI, by right clicking the horizontal line next to the line number.
- Using the `dbstop` command:

```matlab
% Create an unrestricted breakpoint:
dbstop in file at location
% Create a conditional breakpoint:
dbstop in file at location if expression

% Examples and special cases:
dbstop in fit at 99 % Standard unrestricted breakpoint.
dbstop in fit at 99 if nargin==3 % Standard conditional breakpoint.
dbstop if error % This special type of breakpoint is not limited to a specific file, and % will trigger "whenever" an error is encountered in "debuggable" code.
dbstop in file % This will create an unrestricted breakpoint on the first executable line % of "file".
dbstop if naninf % This special breakpoint will trigger whenever a computation result % contains either a NaN (indicates a division by 0) or an Inf
```

- Using keyboard shortcuts: the default key for creating a standard breakpoint on Windows is `F12`; the default key for conditional breakpoints is `unset`. 

https://riptutorial.com/
Disabling and Re-enabling Breakpoints

Disable a breakpoint to temporarily ignore it: disabled breakpoints do not pause execution. Disabling a breakpoint can be done in several ways:

- Right click on the red/yellow breakpoint circle > Disable Breakpoint.
- Left click on a conditional (yellow) breakpoint.
- In the Editor tab > Breakpoints > Enable\Disable.

Removing Breakpoints

All breakpoints remain in a file until removed, either manually or automatically. Breakpoints are cleared automatically when ending the MATLAB session (i.e. terminating the program). Clearing breakpoints manually is done in one of the following ways:

- Using the dbclear command:

  dbclear all
  dbclear in file
  dbclear in file at location
  dbclear if condition

- Left clicking a standard breakpoint icon, or a disabled conditional breakpoint icon.
- Right clicking on any breakpoint > Clear Breakpoint.
- In the Editor tab > Breakpoints > Clear All.
- In pre-R2015b versions of MATLAB, using the command clear.

Resuming Execution

When execution is paused at a breakpoint, there are two ways to continue executing the program:

- Execute the current line and pause again before the next line.

  F10 in the Editor, dbstep in the Command Window, "Step" in Ribbon > Editor > DEBUG.

- Execute until the next breakpoint (if there are no more breakpoints, the execution proceeds until the end of the program).

  F12 in the Editor, dbcont in the Command Window, "Continue" in Ribbon > Editor > DEBUG.

1 - default on Windows.

Debugging Java code invoked by MATLAB

https://riptutorial.com/
Overview

In order to debug Java classes that are called during MATLAB execution, it is necessary to perform two steps:

1. Run MATLAB in JVM debugging mode.
2. Attach a Java debugger to the MATLAB process.

When MATLAB is started in JVM debugging mode, the following message appears in the command window:

```
JVM is being started with debugging enabled.
Use "jdb -connect com.sun.jdi.SocketAttach:port=4444" to attach debugger.
```

Windows:

Create a shortcut to the MATLAB executable (matlab.exe) and add the -jdb flag at the end as shown below:
When running MATLAB using this shortcut JVM debugging will be enabled.

Alternatively the `java.opts` file can be created/updated. This file is stored in "matlab-root\bin\arch", where "matlab-root" is the MATLAB installation directory and "arch" is the architecture (e.g. "win32").

The following should be added in the file:

```
-Xdebug
-Xrunjdwp:transport=dt_socket,address=1044,server=y,suspend=n
```

**Debugger end**

**IntelliJ IDEA**

Attaching this debugger requires the creation of a "remote debugging" configuration with the port exposed by MATLAB:
Then the debugger is started:

If everything is working as expected, the following message will appear in the console:
Read Debugging online: https://riptutorial.com/matlab/topic/1045/debugging
Chapter 6: Documenting functions

Remarks

- Help text can be located before or after the function line, as long as there is not code between the function line and the start of the help text.
- Capitalization of the function name only bolds the name, and is not required.
- If a line is prepended with See also, any names on the line that match the name of a class or function on the search path will automatically link to the documentation of that class/function.
  - Global functions can be referred to here by preceding their name with a \\.
  - Otherwise, the names will first try and resolve to member functions.
- Hyperlinks of the form <a href="matlab:web('url')">Name</a> are allowed.

Examples

Simple Function Documentation

```matlab
function output = mymult(a, b)
% MYMULT Multiply two numbers.
% output = MYMULT(a, b) multiplies a and b.
% See also fft, foo, sin.
% For more information, see Google.
output = a * b;
end
```

help mymult then provides:

- **mymult** Multiply two numbers.

- **output** = **mymult**(a, b) multiplies a and b.

- See also fft, foo, sin.

- For more information, see [Google](https://google.com).

**fft** and **sin** automatically link to their respective help text, and Google is a link to [google.com](https://google.com). **foo** will not link to any documentation in this case, as long as there is not a documented function/class by the name of **foo** on the search path.

Local Function Documentation

In this example, documentation for the local function **baz** (defined in **foo.m**) can be accessed either by the resulting link in help **foo**, or directly through help **foo>baz**.

```matlab
function bar = foo
```
Obtaining a function signature

It is often helpful to have MATLAB print the 1st line of a function, as this usually contains the function signature, including inputs and outputs:

dbtype <functionName> 1

Example:

>> dbtype fit

1   function [fitobj,goodness,output,warnstr,errstr,convmsg] = fit(xdatain,ydatain,fittypeobj,varargin)

Documenting a Function with an Example Script

To document a function, it is often helpful to have an example script which uses your function. The publish function in Matlab can then be used to generate a help file with embedded pictures, code, links, etc. The syntax for documenting your code can be found here.

The Function  This function uses a "corrected" FFT in Matlab.

function out_sig = myfft(in_sig)

out_sig = fftshift(fft(ifftshift(in_sig)));

end

The Example Script  This is a separate script which explains the inputs, outputs, and gives an example explaining why the correction is necessary. Thanks to Wu, Kan, the original author of this function.

```matlab
%% myfft
% This function uses the "proper" fft in matlab. Note that the fft needs to
% be multiplied by dt to have physical significance.
% For a full description of why the FFT should be taken like this, refer
% to: Why_use_fftshift_fft_fftshift_x--in-Matlab-instead-of-fft-x--
% help folder of this code. Additional information can be found:
% % Inputs
```
% *in_sig* - 1D signal
% Outputs
% *out_sig* - corrected FFT of *in_sig*
% Examples
% Generate a signal with an analytical solution. The analytical solution is
% then compared to the fft then to myfft. This example is a modified
% version given by Wu, Kan given in the link aboce.
%
% Set parameters
fs = 500;           %sampling frequency
dt = 1/fs;          %time step
T=1;                %total time window
t = -T/2:dt:T/2-dt; %time grids
df = 1/T;           %freq step
Fmax = 1/2/dt;      %freq window
f = -Fmax:df:Fmax-df; %freq grids, not used in our examples, could be used by plot(f, X)
%
% Generate Gaussian curve
Bx = 10; A = sqrt(log(2))/(2*pi*Bx);    %Characteristics of Gaussian curve
x = exp(-t.^2/2/A^2);                   %Create Gaussian Curve
%
% Generate Analytical solution
Xan = A*sqrt(2*pi)*exp(-2*pi^2*f.^2*A^2); %X(f), real part of the analytical Fourier transform
% of x(t)

%
% Take FFT and corrected FFT then compare
Xfft = dt * fftshift(fft(x));    %FFT
Xfinal = dt * myfft(x);         %Corrected FFT
hold on
plot(f,Xan);
plot(f,real(Xfft));
plot(f,real(Xfinal),'ro');
title('Comparison of Corrected and Uncorrected FFT');
legend('Analytical Solution','Uncorrected FFT','Corrected FFT');
xlabel('Frequency'); ylabel('Amplitude');
DT = max(f) - min(f);
xlim([-DT/4,DT/4]);

The Output

The publish option can be found under the “Publish” tab, highlighted in the image
Simple Function Documentation below.

Matlab will run the script, and save the images which are displayed, as well as the text generated
by the command line. The output can be saved to many different types of formats, including
HTML, Latex, and PDF.

The output of the example script given above can be seen in the image below.
myfft

This function uses the "proper" fft in matlab. Note that the fft needs to be multiplied by dt to have physical significance. For a full description of why the FFT should be taken like this, refer to: Why_use_fftshift(fft(fftshift(x))) in_Matlab.pdf included in the help folder of this code. Additional information can be found: https://www.mathworks.com/matlabcentral/answers/25473-why-use-fftshift-fft-fftshift-x-in-matlab-instead-of-fft-x--

Contents
- Inputs
- Outputs
- Examples

Inputs
in_sig  - 1D signal

Outputs
out_sig - corrected FFT of in_sig

Examples
Generate a signal with an analytical solution. The analytical solution is then compared to the fft then to myfft. This example is a modified version given by Wu, Kan given in the link above.

Set parameters

```
fs = 500;  % sampling frequency
dt = 1/fs; % time step
T=1;       % total time window
t = -T/2:dt:T/2-dt; % time grids
df = 1/T;   % freq step
Fmax = 1/2/dt; % freq window
f=-Fmax:df:Fmax-df; % freq grids, not used in our examples, could be used by plot(f, X)
```

Generate Gaussian curve

```
Bx = 10; A = sqrt(log(2))/(2*pi*Bx); % Characteristics of Gaussian curve
x = exp(-t.^2/2/A^2); % Create Gaussian Curve
```

Generate Analytical solution

```
Xan = A*sqrt(2*pi)*exp(-2*pi^2*f.^2*A^2); % X(f), real part of the analytical Fourier transform of x(t)
```

Take FFT and corrected FFT then compare

```
Xfft = dt * fftshift(fft(x)); % FFT
Xfinal = dt * myfft(x); % Corrected FFT
hold on
plot(2, Xan);  %...
plot(x, real(Xfft));
plot(x, real(Xfinal), 'ro');
title('Comparison of Corrected and Uncorrected FFT');
legend('Analytical Solution', 'Uncorrected FFT', 'Corrected FFT');
xlabel('Frequency'); ylabel('Amplitude');
DT = max(x) - min(x);
xlim([-DT/4, DT/4]);
```
Chapter 7: Drawing

Examples

Circles

The easiest option to draw a circle, is - obviously - the rectangle function.

```matlab
r = 2;  
c = [3 3];  
pos = [c-r 2*r 2*r];  
rectangle('Position',pos,'Curvature',[1 1])  
axis equal
```

but the curvature of the rectangle has to be set to 1!

The position vector defines the rectangle, the first two values \(x\) and \(y\) are the lower left corner of the rectangle. The last two values define width and height of the rectangle.

```matlab
pos = [ x y width height ]
```

The lower left corner of the circle - yes, this circle has corners, imaginary ones though - is the center \(c = [3 3]\) minus the radius \(r = 2\) which is \([x y] = [1 1]\). Width and height are equal to the diameter of the circle, so \(width = 2*r; height = width;\)
In case the smoothness of the above solution is not sufficient, there is no way around using the obvious way of drawing an actual circle by use of trigonometric functions.

```matlab
// number of points
n = 1000;

// running variable
t = linspace(0, 2*pi, n);

x = c(1) + r*sin(t);
y = c(2) + r*cos(t);

// draw line
line(x, y)

// or draw polygon if you want to fill it with color
// fill(x, y, [1, 1, 1])
axis equal
```
Arrows

Firstly, one can use `quiver`, where one doesn't have to deal with unhandy normalized figure units by use of `annotation`

```matlab
drawArrow = @(x,y) quiver( x(1),y(1),x(2)-x(1),y(2)-y(1),0 )
x1 = [10 30];
y1 = [10 30];
drawArrow(x1,y1); hold on
x2 = [25 15];
y2 = [15 25];
drawArrow(x2,y2)
```
Important is the 5th argument of `quiver`: 0 which disables an otherwise default scaling, as this function is usually used to plot vector fields. (or use the property value pair `AutoScale','off')

One can also add additional features:

```matlab
drawArrow = @(x,y,varargin) quiver( x(1),y(1),x(2)-x(1),y(2)-y(1),0, varargin{:} )
drawArrow(x1,y1); hold on
drawArrow(x2,y2,'linewidth',3,'color','r')
```
If different arrowheads are desired, one needs to use annotations (this answer is may helpful How do I change the arrow head style in quiver plot?).

The arrow head size can be adjust with the 'MaxHeadSize' property. It's not consistent unfortunately. The axes limits need to be set afterwards.

```matlab
x1 = [10 30];
y1 = [10 30];
drawArrow(x1,y1,{MaxHeadSize',0.8,'Color','b','LineWidth',3}); hold on
x2 = [25 15];
y2 = [15 25];
drawArrow(x2,y2,{MaxHeadSize',10,'Color','r','LineWidth',3}); hold on
xlim([1, 100])
ylim([1, 100])
```

There is another tweak for adjustable arrow heads:

```matlab
function [ h ] = drawArrow( x,y,xlimits,ylimits,props )
xlim(xlimits)
ylim(ylimits)

h = annotation('arrow');
set(h,'parent', gca, ...
   'position', [x(1),y(1),x(2)-x(1),y(2)-y(1)], ...
   'HeadLength', 10, 'HeadWidth', 10, 'HeadStyle', 'cback1', ...
   props{:} );
end
```
which you can call from your script as follows:

```matlab
drawArrow(x1,y1,[1, 100],[1, 100],{'Color','b','LineWidth',3}); hold on
drawArrow(x2,y2,[1, 100],[1, 100],{'Color','r','LineWidth',3}); hold on
```

**Ellipse**

To plot an ellipse you can use its equation. An ellipse has a major and a minor axis. Also we want to be able to plot the ellipse on different center points. Therefore we write a function whose inputs and outputs are:

**Inputs:**
- \( r_1, r_2 \): major and minor axis respectively
- \( C \): center of the ellipse \( (cx, cy) \)

**Output:**
- \([x, y]\): points on the circumference of the ellipse

You can use the following function to get the points on an ellipse and then plot those points.

```matlab
function [x,y] = getEllipse(r1,r2,C)
beta = linspace(0,2*pi,100);
x = r1*cos(beta) - r2*sin(beta);
y = r1*cos(beta) + r2*sin(beta);
x = x + C(1,1);
y = y + C(1,2);
end
```

**Example:**

```matlab
[x,y] = getEllipse(1,0.3,[2 3]);
```
Polygon(s)

Create vectors to hold the x- and y-locations of vertices, feed these into `patch`.

**Single Polygon**

```matlab
X=rand(1,4); Y=rand(1,4);
h=patch(X,Y,'red');
```
Multiple Polygons

Each polygon's vertices occupy one column of each of $x$, $y$.

```matlab
X=rand(4,3); Y=rand(4,3);
for i=2:3
    X(:,i)=X(:,i)+(i-1); % create horizontal offsets for visibility
end
h=patch(X,Y,'red');
```

Pseudo 4D plot

A $(m \times n)$ matrix can be represented by a surface by using `surf`;

The color of the surface is automatically set as function of the values in the $(m \times n)$ matrix. If the colormap is not specified, the default one is applied.

A colorbar can be added to display the current colormap and indicate the mapping of data values into the colormap.

In the following example, the $z$ $(m \times n)$ matrix is generated by the function:

https://riptutorial.com/
over the interval \([-\pi, \pi]\). The \(x\) and \(y\) values can be generated using the `meshgrid` function and the surface is rendered as follows:

```matlab
% Create a Figure
figure
% Generate the 'x' and 'y' values in the interval '\([-\pi,\pi]\)'
[x,y] = meshgrid([-pi:.2:pi],[-pi:.2:pi]);
% Evaluate the function over the selected interval
z=x.*y.*sin(x).*cos(y);
% Use surf to plot the surface
S=surf(x,y,z);
xlabel('X Axis');
ylabel('Y Axis');
zlabel('Z Axis');
grid minor
colormap('hot')
colorbar
```

**Figure 1**

Now it could be the case that additional information are linked to the values of the \(z\) matrix and they are store in another \((m \times n)\) matrix.

It is possible to add these additional information on the plot by modifying the way the surface is colored.

This will allows having kinda of 4D plot: to the 3D representation of the surface generated by the first \((m \times n)\) matrix, the fourth dimension will be represented by the data contained in the second \((m \times n)\) matrix.
It is possible to create such a plot by calling `surf` with 4 input:

```
surf(x,y,z,C)
```

where the `C` parameter is the second matrix (which has to be of the same size of `z`) and is used to define the color of the surface.

In the following example, the `C` matrix is generated by the function:

```
C=10*sin(0.5*(x.^2.+y.^2))*33;
```

over the interval \([-\pi,\pi]\)

The surface generated by `C` is

![Surface plot](https://riptutorial.com/65)

**Figure 2**

Now we can call `surf` with four input:

```
figure
surf(x,y,z,C)
% shading interp
xlabel('X Axis');
ylabel('Y Axis');
zlabel('Z Axis');
grid minor
colormap('hot')
```
Comparing Figure 1 and Figure 3, we can notice that:

- the shape of the surface corresponds to the $z$ values (the first $(m \times n)$ matrix)
- the colour of the surface (and its range, given by the colorbar) corresponds to the $c$ values (the first $(m \times n)$ matrix)
Of course, it is possible to swap \( z \) and \( C \) in the plot to have the shape of the surface given by the \( C \) matrix and the color given by the \( z \) matrix:

```matlab
figure
surf(x,y,C,z)
% shading interp
xlabel('X Axis');
ylabel('Y Axis');
zlabel('Z Axis');
grid minor
colormap('hot')
colorbar
```

and to compare Figure 2 with Figure 4
Fast drawing

There are three main ways to do sequential plot or animations: `plot(x,y)`, `set(h, 'XData', y, 'YData', y)` and `animatedline`. If you want your animation to be smooth, you need efficient drawing, and the three methods are not equivalent.

```matlab
% Plot a sin with increasing phase shift in 500 steps
x = linspace(0, 2*pi, 100);
figure
tic
for thetha = linspace(0, 10*pi, 500)
    y = sin(x + thetha);
    plot(x, y);
drawnow
toc
```

I get 5.278172 seconds. The plot function basically deletes and recreates the line object each time. A more efficient way to update a plot is to use the `XData` and `YData` properties of the `Line` object.

```matlab
tic
h = [];  % Handle of line object
for thetha = linspace(0, 10*pi, 500)
    y = sin(x + thetha);
    if isempty(h)
        % If Line still does not exist, create it
        h = plot(x, y);
    else
        % Update the line
        h.XData = x;
        h.YData = y;
    end

drawnow
toc
```
% If Line exists, update it
    set(h , 'YData' , y)
end
drawnow
end
toc

Now I get 2.741996 seconds, much better!

animatedline is a relatively new function, introduced in 2014b. Let's see how it fares:

tic
    h = animatedline;
    for thetha = linspace(0 , 10*pi , 500)
        y = sin(x + thetha);
        clearpoints(h)
        addpoints(h , x , y)
        drawnow
    end
toc

3.360569 seconds, not as good as updating an existing plot, but still better than plot(x,y).

Of course, if you have to plot a single line, like in this example, the three methods are almost equivalent and give smooth animations. But if you have more complex plots, updating existing Line objects will make a difference.

Examples

Random Walk

The following is an example that displays 5 one-dimensional random walks of 200 steps:

```matlab
y = cumsum(rand(200,5) - 0.5);
plot(y)
legend('1', '2', '3', '4', '5')
title('random walks')
```

In the above code, \( y \) is a matrix of 5 columns, each of length 200. Since \( x \) is omitted, it defaults to the row numbers of \( y \) (equivalent to using \( x=1:200 \) as the \( x \)-axis). This way the \texttt{plot} function plots multiple \( y \)-vectors against the same \( x \)-vector, each using a different color automatically.

Univariate Geometric Brownian Motion

The dynamics of the Geometric Brownian Motion (GBM) are described by the following stochastic differential equation (SDE):

\[
dS_t = \mu S_t \, dt + \sigma S_t \, dW_t
\]
I can use the **exact** solution to the SDE

\[
S_t = S_0 \exp \left( \left( \mu - \frac{\sigma^2}{2} \right) t + \sigma W_t \right)
\]

to generate paths that follow a GBM.

---

**Given daily parameters for a year-long simulation**

```matlab
mu = 0.08/250;
sigma = 0.25/sqrt(250);
dt = 1/250;
npaths = 100;
nsteps = 250;
S0 = 23.2;
```

we can get the Brownian Motion (BM) \( W \) starting at 0 and use it to obtain the GBM starting at \( S_0 \)

```matlab
% BM
epsilon = randn(nsteps, npaths);
W = [zeros(1,npaths); sqrt(dt)*cumsum(epsilon)];

% GBM
t = (0:nsteps)'*dt;
Y = bsxfun(@plus, (mu-0.5*sigma.^2)*t, sigma*W);
Y = S0*exp(Y);
```

Which produces the paths

```matlab
plot(Y)
```

---

Chapter 9: For loops

Remarks

Iterate over column vector

A common source of bugs is trying to loop over the elements of a column vector. A column vector is treated like a matrix with one column. (There is actually no distinction in Matlab.) The for loop runs once with the loop variable set to the column.

```matlab
% Prints once: [3, 1]
my_vector = [1; 2; 3];
for i = my_vector
    display(size(i))
end
```

Altering the iteration variable

Altering the iteration variable changes its value for the current iteration, but has no impact on its value in subsequent iterations.

```matlab
% Prints 1, 2, 3, 4, 5
for i = 1:5
    display(i)
    i = 5; % Fail at trying to terminate the loop
end
```

Special case performance of a:b in right-hand side

The basic example treats 1:n as a normal instance of creating a row vector and then iterating over it. For performance reasons, Matlab actually treats any a:b or a:c:b specially by not creating the row vector entirely, but instead creating each element one at a time.

This can be detected by slightly altering the syntax.

```matlab
% Loops forever
for i = 1:1e50
end

% Crashes immediately
for i = [1:1e50]
end
```
Examples

Loop 1 to n

The simplest case is just performing a task for a fixed known number of times. Say we want to display the numbers between 1 to n, we can write:

```matlab
n = 5;
for k = 1:n
    display(k)
end
```

The loop will execute the inner statement(s), everything between the `for` and the `end`, for `n` times (5 in this example):

```
1
2
3
4
5
```

Here is another example:

```matlab
n = 5;
for k = 1:n
    disp(n-k+1:-1:1) % DISP uses a more "clean" way to print on the screen
end
```

this time we use both the `n` and `k` in the loop, to create a "nested" display:

```
5 4 3 2 1
4 3 2 1
3 2 1
2 1
1
```

Iterate over elements of vector

The right-hand side of the assignment in a `for` loop can be any row vector. The left-hand side of the assignment can be any valid variable name. The `for` loop assigns a different element of this vector to the variable each run.

```matlab
other_row_vector = [4, 3, 5, 1, 2];
for any_name = other_row_vector
    display(any_name)
end
```
(The $1:n$ version is a normal case of this, because in Matlab $1:n$ is just syntax for constructing a row vector of $[1, 2, \ldots, n]$.)

Hence, the two following blocks of code are identical:

```matlab
A = [1 2 3 4 5];
for x = A
    disp(x);
end
```

and

```matlab
for x = 1:5
    disp(x);
end
```

And the following are identical as well:

```matlab
A = [1 3 5 7 9];
for x = A
    disp(x);
end
```

and

```matlab
for x = 1:2:9
    disp(x);
end
```

Any row vector will do. They don't have to be numbers.

```matlab
my_characters = 'abcde';
for my_char = my_characters
    disp(my_char)
end
```

will output

```
a
b
c
d
e
```
Iterate over columns of matrix

If the right-hand side of the assignment is a matrix, then in each iteration the variable is assigned subsequent columns of this matrix.

```matlab
some_matrix = [1, 2, 3; 4, 5, 6]; % 2 by 3 matrix
for some_column = some_matrix
    display(some_column)
end
```

(The row vector version is a normal case of this, because in Matlab a row vector is just a matrix whose columns are size 1.)

The output would display

```
1
4
2
5
3
6
```

i.e. each column of the iterated matrix displayed, each column printed on each call of `display`.

Loop over indexes

```matlab
my_vector = [0, 2, 1, 3, 9];
for i = 1:numel(my_vector)
    my_vector(i) = my_vector(i) + 1;
end
```

Most simple things done with `for` loops can be done faster and easier by vectorized operations. For example, the above loop can be replaced by `my_vector = my_vector + 1`.

Nested Loops

Loops can be nested, to preform iterated task within another iterated task. Consider the following loops:

```matlab
ch = 'abc';
m = 3;
for c = ch
    for k = 1:m
        disp([c num2str(k)]) % NUM2STR converts the number stored in k to a charachter, % so it can be concataneted with the letter in c
    end
end
```

we use 2 iterators to display all combinations of elements from abc and 1:m, which yields:

```
a1
b1
c1
a2
...```
We can also use nested loops to combine between tasks to be done each time, and tasks to be
done once in a several iterations:

```
N = 10;
n = 3;
a1 = 0; % the first element in Fibonacci series
a2 = 1; % the second element in Fibonacci series
for j = 1:N
    for k = 1:n
        an = a1 + a2; % compute the next element in Fibonacci series
        a1 = a2;      % save the previous element for the next iteration
        a2 = an;      % save the new element for the next iteration
    end
    disp(an) % display every n'th element
end
```

Here we want to compute all the Fibonacci series, but to display only the \( n \)th element each time,
so we get

```
3
13
55
233
987
4181
17711
75025
317811
1346269
```

Another thing we can do is to use the first (outer) iterator within the inner loop. Here is another example:

```
N = 12;
gap = [1 2 3 4 6];
for j = gap
    for k = 1:j:N
        fprintf('%d ',k) % fprintf prints the number k proceeding to the next the line
    end
    fprintf('
')        % go to the next line
end
```

This time we use the nested loop to format the output, and brake the line only when a new gap (\( j \))
between the elements was introduced. We loop through the gap width in the outer loop and use it
within the inner loop to iterate through the vector:
Notice: Weird same counter nested loops.

This is not something you will see in other programming environments. I came across it some years back and I couldn't understand why it was happening, but after working with MATLAB for some time I was able to figure it out. Look at the code snippet below:

```matlab
for x = 1:10
    for x = 1:10
        fprintf('%d,', x);
    end
    fprintf('
');
end
```

You wouldn't expect this to work properly but it does, producing the following output:

```
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
1,2,3,4,5,6,7,8,9,10,
```

The reason is that, as with everything else in MATLAB, the `x` counter is also a matrix—a vector to be precise. As such, `x` is only a reference to an `array` (a coherent, consecutive memory structure) which is appropriately referenced with every consequent loop (nested or not). The fact that the nested loop uses the same identifier makes no difference to how values from that array are referenced. The only problem is that within the nested loop the outer `x` is hidden by the nested (local) `x` and therefore cannot be referenced. However, the functionality of the nested loop structure remains intact.

Chapter 10: Fourier Transforms and Inverse Fourier Transforms

Syntax

1. \( Y = \text{fft}(X) \) \%computes the FFT of Vector or Matrix \( X \) using a default Transform Length of 256 (to be confirmed for version)

2. \( Y = \text{fft}(X,n) \) \%computes the FFT of \( X \) using \( n \) as Transform Length, \( n \) must be a 2-power based number. If the length of \( X \) is less than \( n \), then Matlab will automatically pad \( X \) with zeros such that \( \text{length}(X) = n \)

3. \( Y = \text{fft}(X,n,dim) \) \%computes the FFT of \( X \) using \( n \) as Transform Length along dimension \( dim \) (can be 1 or 2 for horizontal or vertical respectively)

4. \( Y = \text{fft2}(X) \) \% Compute the 2D FFT of \( X \)

5. \( Y = \text{fftn}(X, \text{dim}) \) \% Compute the dim-dimensional FFT of \( X \), with respect to the vector of dimensions \( \text{dim} \).

6. \( y = \text{ifft}(X) \) \%computes the Inverse of FFT of \( X \) (which is a matrix/vector of numbers) using the default 256 Transform Length

7. \( y = \text{ifft}(X,n) \) \%computes the IFFT of \( X \) using \( n \) as Transform Length

8. \( y = \text{ifft}(X,n,dim) \) \%computes the IFFT of \( X \) using \( n \) as Transform Length over dimension \( dim \) (can be 1 or 2 for horizontal or vertical respectively)

9. \( y = \text{ifft}(X,n,dim,'symmetric') \) \%The Symmetric option causes ifft to treat \( X \) as conjugate symmetric along the active dimension. This option is useful when \( X \) is not exactly conjugate symmetric, merely because of round-off error.

10. \( y = \text{ifft2}(X) \) \% Compute the inverse 2D ft of \( X \)

11. \( y = \text{fftn}(X,\text{dim}) \) \%Compute the inverse dim-dimensional fft of \( X \).

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>( X )</td>
<td>this is your input Time-Domain signal, it should be a vector of numerics.</td>
</tr>
<tr>
<td>( n )</td>
<td>this is the NFFT parameter known as Transform Length, think of it as resolution of your FFT result, it MUST be a number that is a power of 2 (i.e. 64,128,256...2^N)</td>
</tr>
</tbody>
</table>
### Parameter Description

**dim**
This is the dimension you want to compute FFT on, use 1 if you want to compute your FFT in the horizontal direction and 2 if you want to compute your FFT in the vertical direction - Note this parameter is usually left blank, as the function is capable of detecting the direction of your vector.

### Remarks
Matlab FFT is a very parallelized process capable of handling large amounts of data. It can also use the GPU to huge advantage.

\[
\text{ifft(fft(X))} = X
\]

The above statement is true if rounding errors are omitted.

### Examples

#### Implement a simple Fourier Transform in Matlab

Fourier Transform is probably the first lesson in Digital Signal Processing, it's application is everywhere and it is a powerful tool when it comes to analyze data (in all sectors) or signals. Matlab has a set of powerful toolboxes for Fourier Transform. In this example, we will use Fourier Transform to analyze a basic sine-wave signal and generate what is sometimes known as a Periodogram using FFT:

```matlab
%Signal Generation
A1=10;                % Amplitude 1
A2=10;                % Amplitude 2
w1=2*pi*0.2;          % Angular frequency 1
w2=2*pi*0.225;        % Angular frequency 2
Ts=1;                 % Sampling time
N=64;                 % Number of process samples to be generated
K=5;                  % Number of independent process realizations
sgm=1;                % Standard deviation of the noise
n=repmat([0:N-1].',1,K);             % Generate resolution
phi1=repmat(rand(1,K)*2*pi,N,1);     % Random phase matrix 1
phi2=repmat(rand(1,K)*2*pi,N,1);     % Random phase matrix 2
x=A1*sin(w1*n*Ts+phi1)+A2*sin(w2*n*Ts+phi2)+sgm*randn(N,K);   % Resulting Signal
NFFT=256;            % FFT length
F=fft(x,NFFT);       % Fast Fourier Transform Result
Z=1/N*abs(F).^2;     % Convert FFT result into a Periodogram
```
Note that the Discrete Fourier Transform is implemented by Fast Fourier Transform (fft) in Matlab, both will yield the same result, but FFT is a fast implementation of DFT.

In the Discrete Fourier Transform, we transform a signal from the time domain to the frequency domain. The function `fft` is used to perform this transformation.

```matlab
figure
w=linspace(0,2,NFFT);
plot(w,10*log10(Z)),grid;
xlabel('w [\pi rad/s]')
ylabel('Z(f) [dB]')
title('Frequency Range: [ 0 , \omega_s ]')
```

Inverse Fourier Transforms

One of the major benefit of Fourier Transform is its ability to inverse back in to the Time Domain without losing information. Let us consider the same Signal we used in the previous example:

```matlab
A1=10;                % Amplitude 1
A2=10;                % Amplitude 2
w1=2*pi*0.2;          % Angular frequency 1
w2=2*pi*0.225;        % Angular frequency 2
Ts=1;                 % Sampling time
N=64;                 % Number of process samples to be generated
K=1;                  % Number of independent process realizations
sgm=1;                % Standard deviation of the noise
n=repmat([0:N-1].',1,K); % Generate resolution
phi1=repmat(rand(1,K)*2*pi,N,1); % Random phase matrix 1
phi2=repmat(rand(1,K)*2*pi,N,1); % Random phase matrix 2
x=A1*sin(w1*n*Ts+phi1)+A2*sin(w2*n*Ts+phi2)+sgm*randn(N,K); % Resulting Signal
NFFT=256;            % FFT length
F=fft(x,NFFT);       % FFT result of time domain signal
```
If we open \( F \) in Matlab, we will find that it is a matrix of complex numbers, a real part and an imaginary part. By definition, in order to recover the original Time Domain signal, we need both the Real (which represents Magnitude variation) and the Imaginary (which represents Phase variation), so to return to the Time Domain, one may simply want to:

\[
TD = \text{ifft}(F, \text{NFFT}); \quad \% \text{Returns the Inverse of } F \text{ in Time Domain}
\]

Note here that TD returned would be length 256 because we set NFFT to 256, however, the length of \( x \) is only 64, so Matlab will pad zeros to the end of the TD transform. So for example, if NFFT was 1024 and the length was 64, then TD returned will be 64 + 960 zeros. Also note that due to floating point rounding, you might get something like 3.1 \times 10^{-20} but for general purposes: For any \( X \), \text{ifft}(\text{fft}(X)) \text{ equals } X \text{ to within roundoff error.}

Let us say for a moment that after the transformation, we did something and are only left with the REAL part of the FFT:

\[
R = \text{real}(F); \quad \% \text{Give the Real Part of the FFT}
TDR = \text{ifft}(R, \text{NFFT}); \quad \% \text{Give the Time Domain of the Real Part of the FFT}
\]

This means that we are losing the imaginary part of our FFT, and therefore, we are losing information in this reverse process. To preserve the original without losing information, you should always keep the imaginary part of the FFT using \text{imag} and apply your functions to either both or the real part.

```
figure
subplot(3,1,1)
plot(x);xlabel('time samples');ylabel('magnitude');title('Original Time Domain Signal')
subplot(3,1,2)
plot(TD(1:64));xlabel('time samples');ylabel('magnitude');title('Inverse Fourier Transformed - Time Domain Signal')
subplot(3,1,3)
plot(TDR(1:64));xlabel('time samples');ylabel('magnitude');title('Real part of IFFT transformed Time Domain Signal')
```
Images and multidimensional FTs

In medical imaging, spectroscopy, image processing, cryptography and other areas of science and engineering it is often the case that one wishes to compute multidimensional Fourier transforms of images. This is quite straightforward in Matlab: (multidimensional) images are just n-dimensional matrices, after all, and Fourier transforms are linear operators: one just iteratively Fourier transforms along other dimensions. Matlab provides `fft2` and `ifft2` to do this in 2-d, or `fftn` in n-dimensions.

One potential pitfall is that the Fourier transform of images are usually shown "centric ordered", i.e. with the origin of k-space in the middle of the picture. Matlab provides the `fftsft` command to swap the location of the DC components of the Fourier transform appropriately. This ordering notation makes it substantially easier to perform common image processing techniques, one of which is illustrated below.

Zero filling

One "quick and dirty" way to interpolate a small image to a larger size is to Fourier transform it, pad the Fourier transform with zeros, and then take the inverse transform. This effectively interpolates between each pixel with a sinc shaped basis function, and is commonly used to upscale low resolution medical imaging data. Let's start by loading a built-in image example
% Load example image
I = imread('coins.png'); % Load example data -- coins.png is builtin to Matlab
I = double(I); % Convert to double precision -- imread returns integers
imageSize = size(I); % I is a 246 x 300 2D image

% Display it
imagesc(I); colormap gray; axis equal;
% imagesc displays images scaled to maximum intensity

We can now obtain the Fourier transform of I. To illustrate what \texttt{fftshift} does, let's compare the two methods:

% Fourier transform
% Obtain the centric- and non-centric ordered Fourier transform of I
k = fftshift(fft2(fftshift(I)));
kwrong = fft2(I);

% Just for the sake of comparison, show the magnitude of both transforms:
figure; subplot(2,1,1);
imagesc(abs(k),[0 1e4]); colormap gray; axis equal;
subplot(2,1,2);
imagesc(abs(kwrong),[0 1e4]); colormap gray; axis equal;
%(The second argument to \texttt{imagesc} sets the colour axis to make the difference clear).
We now have obtained the 2D FT of an example image. To zero-fill it, we want to take each k-space, pad the edges with zeros, and then take the back transform:

```matlab
%Zero fill
kzf = zeros(imageSize .* 2); %Generate a 492x600 empty array to put the result in
kzf(end/4:3*end/4-1,end/4:3*end/4-1) = k; %Put k in the middle
kzfwrong = zeros(imageSize .* 2); %Generate a 492x600 empty array to put the result in
kzfwrong(end/4:3*end/4-1,end/4:3*end/4-1) = kwrong; %Put k in the middle

%Show the differences again
%Just for the sake of comparison, show the magnitude of both transforms:
figure; subplot(2,1,1);
imagesc(abs(kzf),[0 1e4]); colormap gray; axis equal;
subplot(2,1,2);
imagesc(abs(kzfwrong),[0 1e4]); colormap gray; axis equal;
%(The second argument to imagesc sets the colour axis to make the difference clear).
```

At this point, the result fairly unremarkable:
Once we then take the back-transforms, we can see that (correctly!) zero-filling data provides a sensible method for interpolation:

```matlab
% Take the back transform and view
Izf = fftshift(ifft2(ifftshift(kzf)));  
Izfwrong = ifft2(kzfwrong);

figure; subplot(1,3,1);  
imagesc(abs(Izf)); colormap gray; axis equal;  
title('Zero-filled image');  
subplot(1,3,2);  
imagesc(abs(Izfwrong)); colormap gray; axis equal;  
title('Incorrectly zero-filled image');  
subplot(1,3,3);  
imagesc(I); colormap gray; axis equal;  
title('Original image');  
set(gcf,'color','w');
```

https://riptutorial.com/
Note that the zero-filled image size is double that of the original. One can zero fill by more than a factor of two in each dimension, although obviously doing so does not arbitrarily increase the size of an image.

**Hints, tips, 3D and beyond**

The above example holds for 3D images (as are often generated by medical imaging techniques or confocal microscopy, for example), but require `fft2` to be replaced by `fftn(I, 3)`, for example. Due to the somewhat cumbersome nature of writing `fftshift(fft(fftshift(... several times, it is quite common to define functions such as `fft2c` locally to provide easier syntax locally -- such as:

```matlab
function y = fft2c(x)
    y = fftshift(fft2(fftshift(x)));
```

Note that the FFT is fast, but large, multidimensional Fourier transforms will still take time on a
modern computer. It is additionally inherently complex: the magnitude of k-space was shown above, but the phase is absolutely vital; translations in the image domain are equivalent to a phase ramp in the Fourier domain. There are several far more complex operations that one may wish to do in the Fourier domain, such as filtering high or low spatial frequencies (by multiplying it with a filter), or masking out discrete points corresponding to noise. There is correspondingly a large quantity of community generated code for handling common Fourier operations available on Matlab’s main community repository site, the File Exchange.

Read Fourier Transforms and Inverse Fourier Transforms online:
Chapter 11: Functions

Examples

Base example

The following MATLAB script shows how to define and call a basic function:

*myFun.m*:

```matlab
function [out1] = myFun(arg0, arg1)
    out1 = arg0 + arg1;
end
```

*terminal*:

```matlab
>> res = myFun(10, 20)
res =
    30
```

Multiple outputs

The following MATLAB script shows how to return multiple outputs in a single function:

*myFun.m*:

```matlab
function [out1, out2, out3] = myFun(arg0, arg1)
    out1 = arg0 + arg1;
    out2 = arg0 * arg1;
    out3 = arg0 - arg1;
end
```

*terminal*:

```matlab
>> [res1, res2, res3] = myFun(10, 20)
res1 =
    30
res2 =
    200
res3 =
   -10
```

However MATLAB will return only the first value when assigned to a single variable
The following example shows how to get a specific output

```plaintext
>> [~, res] = myFun(10, 20)

res =

200
```

**nargin, nargout**

In the body of a function `nargin` and `nargout` indicate respectively the actual number of input and output supplied in the call.

We can for example control the execution of a function based on the number of provided input.

*myVector.m:*

```plaintext
function [res] = myVector(a, b, c)
    % Roughly emulates the colon operator
    switch nargin
        case 1
            res = [0:a];
        case 2
            res = [a:b];
        case 3
            res = [a:b:c];
        otherwise
            error('Wrong number of params');
    end
end
```

*terminal:*

```plaintext
>> myVector(10)

ans =

    0     1     2     3     4     5     6     7     8     9    10

>> myVector(10, 20)

ans =

   10    11    12    13    14    15    16    17    18    19    20

>> myVector(10, 2, 20)

ans =
```

https://riptutorial.com/
In a similar way we can control the execution of a function based on the number of output parameters.

`myIntegerDivision`:

```matlab
function [qt, rm] = myIntegerDivision(a, b)
    qt = floor(a / b);
    if nargout == 2
        rm = rem(a, b);
    end
end
```

**terminal:**

```matlab
>> q = myIntegerDivision(10, 7)
q = 1

>> [q, r] = myIntegerDivision(10, 7)
q = 1
r = 3
```

Chapter 12: Graphics: 2D and 3D Transformations

Examples

2D Transformations

In this Example we are going to take a square shaped line plotted using line and perform transformations on it. Then we are going to use the same transformations but in different order and see how it influences the results.

First we open a figure and set some initial parameters (square point coordinates and transformation parameters)

```matlab
%Open figure and create axis
Figureh=figure('NumberTitle','off','Name','Transformation Example',...
    'Position',[200 200 700 700]); %bg is set to red so we know that we can only see the axes
Axesh=axes('XLim',[-8 8],'YLim',[-8,8]);

%Initializing Variables
square=[-0.5 -0.5;-0.5 0.5;0.5 0.5;0.5 -0.5]; %represented by its vertices
Sx=0.5;
Sy=2;
Tx=2;
Ty=2;
teta=pi/4;
```

Next we construct the transformation matrices (scale, rotation and translation):

```matlab
%Generate Transformation Matrix
S=makehgtform('scale',[Sx Sy 1]);
R=makehgtform('zrotate',teta);
T=makehgtform('translate',[Tx Ty 0]);
```

Next we plot the blue square:

```matlab
%% Plotting the original Blue Square
OriginalSQ=line([square(:,1);square(1,1)],[square(:,2);square(1,2)],'Color','b','LineWidth',3);
grid on; % Applying grid on the figure
hold all; % Holding all Following graphs to current axes
```

Next we will plot it again in a different color (red) and apply the transformations:

```matlab
%% Plotting the Red Square
%Calculate rectangle vertices
HrectTRS=T*R*S;
RedSQ=line([square(:,1);square(1,1)],[square(:,2);square(1,2)],'Color','r','LineWidth',3);
%transformation of the axes
```
AxesTransformation=hgtransform('Parent',gca,'matrix',HrectTRS);
%setting the line to be a child of transformed axes
set(RedSQ,'Parent',AxesTransformation);

The result should look like this:

Now lets see what happens when we change the transformation order:

%% Plotting the Green Square
HrectRST=R*S*T;
GreenSQ=line([square(:,1);square(1,1)],[square(:,2);square(1,2)],'Color','g','LineWidth',3);
AxesTransformation=hgtransform('Parent',gca,'matrix',HrectRST);
set(GreenSQ,'Parent',AxesTransformation);

%% Plotting the Yellow Square
HrectSRT=S*R*T;
YellowSQ=line([square(:,1);square(1,1)],[square(:,2);square(1,2)],'Color','y','LineWidth',3);
AxesTransformation=hgtransform('Parent',gca,'matrix',HrectSRT);
set(YellowSQ,'Parent',AxesTransformation);

https://riptutorial.com/matlab/topic/7418/graphics--2d-and-3d-transformations
Chapter 13: Graphics: 2D Line Plots

Syntax

- plot(Y)
- plot(Y,LineSpec)
- plot(X,Y)
- plot(X,Y,LineSpec)
- plot(X1,Y1, X2,Y2, ..., Xn,Yn)
- plot(X1,Y1,LineSpec1, X2,Y2,LineSpec2, ..., Xn,Yn,LineSpecn)
- plot(___, Name,Value)
- h = plot(__)

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>x-values</td>
</tr>
<tr>
<td>Y</td>
<td>y-values</td>
</tr>
<tr>
<td>LineSpec</td>
<td>Line style, marker symbol, and color, specified as a string</td>
</tr>
<tr>
<td>Name,Value</td>
<td>Optional pairs of name-value arguments to customize line properties</td>
</tr>
<tr>
<td>h</td>
<td>handle to line graphics object</td>
</tr>
</tbody>
</table>

Remarks

Examples

Multiple lines in a single plot

In this example we are going to plot multiple lines onto a single axis. Additionally, we choose a different appearance for the lines and create a legend.
In the above example, we plotted the lines with a single `plot`-command. An alternative is to use separate commands for each line. We need to `hold` the contents of a figure with `hold on` the latest before we add the second line. Otherwise the previously plotted lines will disappear from the figure. To create the same plot as above, we can use these following commands:

```matlab
figure; hold on;
plot(x,y1);
plot(x,y2,'--');
plot(x,y3,'-.');
```

The resulting figure looks like this in both cases:

**Quadrate functions with different curvatures**

- $f(x) = x^2$
- $f(x) = 2x^2$
- $f(x) = 4x^2$

Split line with NaNs

Interleave your $y$ or $x$ values with NaNs

https://riptutorial.com/
Custom colour and line style orders

In MATLAB, we can set new default custom orders, such as a colour order and a line style order. That means new orders will be applied to any figure that is created after these settings have been applied. The new settings remains until MATLAB session is closed or new settings has been made.

Default colour and line style order

By default, MATLAB uses a couple of different colours and only a solid line style. Therefore, if `plot` is called to draw multiple lines, MATLAB alternates through a colour order to draw lines in different colours.
We can obtain the default colour order by calling `get` with a global handle 0 followed by this attribute `DefaultAxesColorOrder`:

```matlab
>> get(0, 'DefaultAxesColorOrder')
an
0 0.4470 0.7410
0.8500 0.3250 0.0980
0.9290 0.6940 0.1250
0.4940 0.1840 0.5560
0.4660 0.6740 0.1880
0.3010 0.7450 0.9330
0.6350 0.0780 0.1840
```

**Custom colour and line style order**

Once we have decided to set a custom colour order AND line style order, MATLAB must alternate through both. The first change MATLAB applies is a colour. When all colours are exhausted, MATLAB applies the next line style from a defined line style order and set a colour index to 1. That means MATLAB will begin to alternate through all colours again but using the next line style in its order. When all line styles and colours are exhausted, obviously MATLAB begins to cycle from the beginning using the first colour and the first line style.

For this example, I have defined an input vector and an anonymous function to make plotting figures a little bit easier:

```matlab
F = @(a,x) bsxfun(@plus, -0.2*x(:).^2, a);
x = (-5:5/100:5-5/100)';
```

To set a new colour or a new line style orders, we call `set` function with a global handle 0 followed
by an attribute DefaultAxesColorOrder; LineStyleOrder. The following command sets a new colour order to black, red and blue, respectively:

```matlab
set(0, 'DefaultAxesColorOrder', [0 0 0; 1 0 0; 0 0 1]);
plot(x, F([1 2 3 4 5 6],x));
```

As you can see, MATLAB alternates only through colours because line style order is set to a solid line by default. When a set of colours is exhausted, MATLAB starts from the first colour in the colour order.

The following commands set both colour and line style orders:

```matlab
set(0, 'DefaultAxesColorOrder', [0 0 0; 1 0 0; 0 0 1]);
set(0, 'DefaultAxesLineStyleOrder', {'-' '--'});
plot(x, F([1 2 3 4 5 6],x));
```
Now, MATLAB alternates through different colours and different line styles using colour as most frequent attribute.

Read Graphics: 2D Line Plots online: https://riptutorial.com/matlab/topic/426/graphics--2d-line-plots
Chapter 14: Image processing

Examples

Basic image I/O

```matlab
>> img = imread('football.jpg');
```

Use `imread` to read image files into a matrix in MATLAB. Once you `imread` an image, it is stored as an ND-array in memory:

```matlab
>> size(img)
ans =
    256   320     3
```

The image `football.jpg` has 256 rows and 320 columns and it has 3 color channels: Red, Green, and Blue.

You can now mirror it:

```matlab
>> mirrored = img(:, end:-1:1, :);  %// like mirroring any ND-array in Matlab
```

And finally, write it back as an image using `imwrite`:

```matlab
>> imwrite(mirrored, 'mirrored_football.jpg');
```

Retrieve Images from the Internet

As long as you have an internet connection, you can read images from an hyperlink

```matlab
I=imread('https://cdn.sstatic.net/Sites/stackoverflow/company/img/logos/so/so-logo.png');
```

Filtering Using a 2D FFT

Like for 1D signals, it’s possible to filter images by applying a Fourier transformation, multiplying with a filter in the frequency domain, and transforming back into the space domain. Here is how you can apply high- or low-pass filters to an image with Matlab:

Let `image` be the original, unfiltered image, here’s how to compute its 2D FFT:

```matlab
ft = fftshift(fft2(image));
```

Now to exclude a part of the spectrum, one need to set its pixel values to 0. The spatial frequency contained in the original image is mapped from the center to the edges (after using `fftshift`). To exclude the low frequencies, we will set the central circular area to 0.
Here's how to generate a disc-shaped binary mask with radius $D$ using built-in function:

```matlab
[x y ~] = size(ft);
D = 20;
mask = fspecial('disk', D) == 0;
mask = imresize(padarray(mask, [floor((x/2)-D) floor((y/2)-D)], 1, 'both'), [x y]);
```

Masking the frequency domain image can be done by multiplying the FFT point-wise with the binary mask obtained above:

```matlab
masked_ft = ft .* mask;
```

Now, let's compute the inverse FFT:

```matlab
filtered_image = ifft2(ifftshift(masked_ft), 'symmetric');
```

The high frequencies in an image are the sharp edges, so this high-pass filter can be used to sharpen images.

**Image Filtering**

Let's say you have an image `rgbImg`, e.g., read in using `imread`.

```matlab
>> rgbImg = imread('pears.png');
>> figure, imshow(rgbImg), title('Original Image')
```
Use `fspecial` to create a 2D filter:

```matlab
>> h = fspecial('disk', 7);
>> figure, imshow(h, []), title('Filter')
```

Use `imfilter` to apply the filter on the image:

```matlab
>> filteredRgbImg = imfilter(rgbImg, h);
>> figure, imshow(filteredRgbImg), title('Filtered Image')
```
Measuring Properties of Connected Regions

Starting with a binary image, `bwImg`, which contains a number of connected objects.

```matlab
>> bwImg = imread('blobs.png');
>> figure, imshow(bwImg), title('Binary Image')
```
To measure properties (e.g., area, centroid, etc) of every object in the image, use `regionprops`

```matlab
>> stats = regionprops(bwImg, 'Area', 'Centroid');
```

`stats` is a struct array which contains a struct for every object in the image. Accessing a measured property of an object is simple. For example, to display the area of the first object, simply,

```matlab
>> stats(1).Area
ans =
35
```

Visualize the object centroids by overlaying them on the original image.

```matlab
>> figure, imshow(bwImg), title('Binary Image With Centroids Overlaid')
>> hold on
>> for i = 1:size(stats)
    scatter(stats(i).Centroid(1), stats(i).Centroid(2), 'filled');
end
```
Binary Image With Centroids Overlaid

Chapter 15: Initializing Matrices or arrays

Introduction

Matlab has three important functions to create matrices and set their elements to zeroes, ones, or the identity matrix. (The identity matrix has ones on the main diagonal and zeroes elsewhere.)

Syntax

- \( Z = \text{zeros}(sz,\text{datatype},\text{arraytype}) \)
- \( X = \text{ones}(sz,\text{datatype}) \)
- \( I = \text{eye}(sz,\text{datatype}) \)

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>( sz )</td>
<td>n (for an ( n \times n ) matrix)</td>
</tr>
<tr>
<td>( sz )</td>
<td>n, m (for an ( n \times m ) matrix)</td>
</tr>
<tr>
<td>( sz )</td>
<td>m,n,...,k (for an ( m \times n \times \ldots \times k ) matrix)</td>
</tr>
<tr>
<td>( \text{datatype} )</td>
<td>'double' (default), 'single', 'int8', 'uint8', 'int16', 'uint16', 'int32', 'uint32', 'int64', or 'uint64'</td>
</tr>
<tr>
<td>( \text{arraytype} )</td>
<td>'distributed'</td>
</tr>
<tr>
<td>( \text{arraytype} )</td>
<td>'codistributed'</td>
</tr>
<tr>
<td>( \text{arraytype} )</td>
<td>'gpuArray'</td>
</tr>
</tbody>
</table>

Remarks

These functions will create a matrix of doubles, by default.

Examples

Creating a matrix of 0s

\[
\begin{align*}
z1 &= \text{zeros}(5); & \text{Create a 5-by-5 matrix of zeroes} \\
z2 &= \text{zeros}(2,3); & \text{Create a 2-by-3 matrix}
\end{align*}
\]
Creating a matrix of 1s

```matlab
o1 = ones(5); % Create a 5-by-5 matrix of ones
o2 = ones(1,3); % Create a 1-by-3 matrix / vector of size 3
```

Creating an identity matrix

```matlab
i1 = eye(3); % Create a 3-by-3 identity matrix
i2 = eye(5,6); % Create a 5-by-6 identity matrix
```

Read Initializing Matrices or arrays online: https://riptutorial.com/matlab/topic/8049/initializing-matrices-or-arrays
Chapter 16: Integration

Examples

Integral, integral2, integral3

1 dimensional

To integrate a one dimensional function

\[ f = \sin(x)^3 + 1; \]

within the range

\[ \text{xmin} = 2; \]
\[ \text{xmax} = 8; \]

one can call the function

\[ q = \text{integral}(f, \text{xmin}, \text{xmax}); \]

it's also possible to set boundarys for relative and absolute errors

\[ q = \text{integral}(f, \text{xmin}, \text{xmax}, '\text{RelTol}',10^{-6}, '\text{AbsTol}',10^{-4}); \]

2 dimensional

If one wants to integrate a two dimensional function

\[ f = \sin(x)^y; \]

within the range

\[ \text{xmin} = 2; \]
\[ \text{xmax} = 8; \]
\[ \text{ymin} = 1; \]
\[ \text{ymax} = 4; \]

one calls the function

\[ q = \text{integral2}(f, \text{xmin}, \text{xmax}, \text{ymin}, \text{ymax}); \]

Like in the other case it's possible to limit the tolerances

\[ q = \text{integral2}(f, \text{xmin}, \text{xmax}, \text{ymin}, \text{ymax}, '\text{RelTol}',10^{-6}, '\text{AbsTol}',10^{-4}); \]
3 dimensional

Integrating a three dimensional function

\[ f = @(x,y,z) \sin(x) \cdot y - \cos(z) \;

within the range

\[ \begin{align*}
    \text{xmin} &= 2; \\
    \text{xmax} &= 8; \\
    \text{ymin} &= 1; \\
    \text{ymax} &= 4; \\
    \text{zmin} &= 6; \\
    \text{zmax} &= 13;
\end{align*} \]

is performed by calling

\[ q = \text{integral3}(f, \text{xmin, xmax, ymin, ymax, zmin, zmax}); \]

Again it's possible to limit the tolerances

\[ q = \text{integral3}(f, \text{xmin, xmax, ymin, ymax, zmin, zmax, 'RelTol', 10e-6, 'AbsTol', 10^{-4}}); \]

Read Integration online: https://riptutorial.com/matlab/topic/7022/integration
Chapter 17: Interpolation with MATLAB

Syntax

1. `zy = interp1(x,y);`
2. `zy = interp1(x,y,'method');`
3. `zy = interp1(x,y,'method','extrapolation');`
4. `zy = interp1(x,y,zx);`
5. `zy = interp1(x,y,zx,'method');`
6. `zy = interp1(x,y,zx,'method','extrapolation');`

Examples

Piecewise interpolation 2 dimensional

We initialize the data:

```
[X,Y] = meshgrid(1:2:10);
Z = X.*cos(Y) - Y.*sin(X);
```

The surface looks like the following.

Now we set the points where we want to interpolate:

```
[Vx,Vy] = meshgrid(1:0.25:10);
```
We now can perform nearest interpolation,

\[ V_z = \text{interp2}(X,Y,Z,Vx,Vy,'nearest'); \]

linear interpolation,

\[ V_z = \text{interp2}(X,Y,Z,Vx,Vy,'linear'); \]
cubic interpolation

Vz = interp2(X,Y,Z,Vx,Vy,'cubic');

or spline interpolation:

Vz = interp2(X,Y,Z,Vx,Vy,'spline');
Piecewise interpolation 1 dimensional

We will use the following data:

```matlab
x = 1:5:50;
y = randi([-10 10],1,10);
```
Hereby \( x \) and \( y \) are the coordinates of the data points and \( z \) are the points we need information about.

\[
z = 0:0.25:50;
\]

One way to find the y-values of \( z \) is piecewise linear interpolation.

\[
z_{y} = \text{interp1}(x,y,z,'linear');
\]
Hereby one calculates the line between two adjacent points and gets \( z_y \) by assuming that the point would be an element of those lines.

`interp1` provides other options too like nearest interpolation,

\[
z_y = \text{interp1}(x,y,z, 'nearest');
\]
next interpolation,

\[ \text{z}_y = \text{interp1}(x, y, z, \text{'next'}) \]
Shape-preserving piecewise cubic interpolation,

\[ z_y = \text{interp1}(x, y, z, 'pchip'); \]
cubic convolution, \( z_y = \text{interp1}(x,y,z, \text{'}v5cubic\text{'}) \);

and spline interpolation

\( z_y = \text{interp1}(x,y,z, \text{'}spline\text{'}) \);
Hereby are nearest, next and previous interpolation piecewise constant interpolations.

**Polynomial interpolation**

We initialize the data we want to interpolate:

```matlab
x = 0:0.5:10;
y = sin(x/2);
```

This means the underlying function for the data in the interval [0,10] is sinusoidal. Now the coefficients of the approximating polynomials are being calculated:

```matlab
p1 = polyfit(x,y,1);
p2 = polyfit(x,y,2);
p3 = polyfit(x,y,3);
p5 = polyfit(x,y,5);
p10 = polyfit(x,y,10);
```

Hereby is \( x \) the x-value and \( y \) the y-value of our data points and the third number is the order/degree of the polynomial. We now set the grid we want to compute our interpolating function on:

```matlab
zx = 0:0.1:10;
```

and calculate the y-values:

```matlab
zy1 = polyval(p1,zx);
zy2 = polyval(p2,zx);
zy3 = polyval(p3,zx);
zy5 = polyval(p5,zx);
zy10 = polyval(p10,zx);
```

One can see that the approximation error for the sample gets smaller when the degree of the polynomial increases.
While the approximation of the straight line in this example has larger errors the order 3 polynomial approximates the sinus function in this intervall relatively good.

The interpolation with order 5 and order 10 polynomials has almost no approximation error. However if we consider the out of sample performance one sees that too high orders tend to
overfit and therefore perform badly out of sample. We set

```matlab
zx = -10:0.1:40;
p10 = polyfit(X,Y,10);
p20 = polyfit(X,Y,20);
```

and

```matlab
zy10 = polyval(p10,zx);
zy20 = polyval(p20,zx);
```

If we take a look at the plot we see that the out of sample performance is best for the order 1 and keeps getting worse with increasing degree.
Read Interpolation with MATLAB online: https://riptutorial.com/matlab/topic/6997/interpolation-with-matlab
Chapter 18: Introduction to MEX API

Examples

Check number of inputs/outputs in a C++ MEX-file

In this example we will write a basic program that checks the number of inputs and outputs passed to a MEX-function.

As a starting point, we need to create a C++ file implementing the "MEX gateway". This is the function executed when the file is called from MATLAB.

**testinputs.cpp**

```cpp
#include "mex.h"

void mexFunction(int nlhs, mxArray *plhs[], int nrhs, const mxArray *prhs[])
{
    // This function will error if number of inputs its not 3 or 4
    // This function will error if number of outputs is more than 1

    // Check inputs:
    if (nrhs < 3 || nrhs > 4) {
        mexErrMsgIdAndTxt("Testinputs:ErrorIdIn",
                       "Invalid number of inputs to MEX file.");
    }

    // Check outputs:
    if (nlhs > 1) {
        mexErrMsgIdAndTxt("Testinputs:ErrorIdOut",
                         "Invalid number of outputs to MEX file.");
    }
}
```

First, we include the `mex.h` header which contains definitions of all the required functions and data types to work with the MEX API. Then we implement the function `mexFunction` as shown, where its signature must not change, independent of the inputs/outputs actually used. The function parameters are as follows:

- `nlhs`: Number of outputs requested.
- `*plhs[]`: Array containing all the outputs in MEX API format.
- `nrhs`: Number of inputs passed.
- `*prhs[]`: Array containing all the inputs in MEX API format.

Next, we check the number of inputs/outputs arguments, and if the validation fails, an error is thrown using `mexErrMsgIdAndTxt` function (it expects a `somename:ID` format identifier, a simple “ID” won’t work).
Once the file is compiled as `mex testinputs.cpp`, the function can be called in MATLAB as:

```matlab
>> testinputs(2,3)
Error using testinputs. Invalid number of inputs to MEX file.

>> testinputs(2,3,5)
>> [~,~] = testinputs(2,3,3)
Error using testinputs. Invalid number of outputs to MEX file.
```

### Input a string, modify it in C, and output it

In this example, we illustrate string manipulation in MATLAB MEX. We will create a MEX-function that accepts a string as input from MATLAB, copy the data into C-string, modify it and convert it back to `mxArray` returned to the MATLAB side.

The main objective of this example is to show how strings can be converted to C/C++ from MATLAB and vice versa.

#### stringIO.cpp

```c
#include "mex.h"
#include <cstring>

void mexFunction(int nlhs, mxArray *plhs[], int nrhs, const mxArray *prhs[])
{
    // check number of arguments
    if (nrhs != 1 || nlhs > 1) {
        mexErrMsgIdAndTxt("StringIO:WrongNumArgs", "Wrong number of arguments.");
    }

    // check if input is a string
    if (mxIsChar(prhs[0])) {
        mexErrMsgIdAndTxt("StringIO:TypeError", "Input is not a string");
    }

    // copy characters data from mxArray to a C-style string (null-terminated)
    char *str = mxArrayToString(prhs[0]);

    // manipulate the string in some way
    if (strcmp("theOneString", str) == 0) {
        str[0] = 'T'; // capitalize first letter
    } else {
        str[0] = ' '; // do something else?
    }

    // return the new modified string
    plhs[0] = mxCreateString(str);

    // free allocated memory
    mxFree(str);
}
```

The relevant functions in this example are:
• `mxIsChar` to test if an `mxArray` is of `mxCHAR` type.
• `mxArrayToString` to copy the data of a `mxArray` string to a `char*` buffer.
• `mxCreateString` to create an `mxArray` string from a `char*`.

As a side note, if you only want to read the string, and not modify it, remember to declare it as `const char*` for speed and robustness.

Finally, once compiled we can call it from MATLAB as:

```matlab
>> mex stringIO.cpp
>> strOut = stringIO('theOneString')
strOut = TheOneString
>> strOut = stringIO('somethingelse')
strOut= somethingelse
```

Pass a 3D matrix from MATLAB to C

In this example we illustrate how to take a double real-type 3D matrix from MATLAB, and pass it to a C `double*` array.

The main objectives of this example are showing how to obtain data from MATLAB MEX arrays and to highlight some small details in matrix storage and handling.

```c
#include "mex.h"

void mexFunction(int  nlhs , mxArray *plhs[], int nrhs, mxArray const *prhs[]){
    // check amount of inputs
    if (nrhs!=1) {
        mexErrMsgIdAndTxt("matrixIn:InvalidInput", "Invalid number of inputs to MEX file.");
    }
    // check type of input
    if( !mxIsDouble(prhs[0]) || mxIsComplex(prhs[0])){
        mexErrMsgIdAndTxt("matrixIn:InvalidType", "Input matrix must be a double, non-complex array.");
    }
    // extract the data
    double const * const matrixAux= static_cast<double const *>(mxGetData(prhs[0]));
    // Get matrix size
    const mwSize *sizeInputMatrix= mxGetDimensions(prhs[0]);
    // allocate array in C. Note: its 1D array, not 3D even if our input is 3D
double* matrixInC= (double*)malloc(sizeInputMatrix[0] *sizeInputMatrix[1])
```

https://riptutorial.com/
The relevant concepts to be aware of:

- MATLAB matrices are all 1D in memory, no matter how many dimensions they have when used in MATLAB. This is also true for most (if not all) main matrix representation in C/C++ libraries, as allows optimization and faster execution.

- You need to explicitly copy matrices from MATLAB to C in a loop.

- MATLAB matrices are stored in column major order, as in Fortran, but C/C++ and most modern languages are row major. It is important to permute the input matrix, or else the data will look completely different.

The relevant function in this example are:

- `mxIsDouble` checks if input is double type.
- `mxIsComplex` checks if input is real or imaginary.
- `mxGetData` returns a pointer to the real data in the input array. NULL if there is no real data.
- `mxGetDimensions` returns an pointer to a `mwSize` array, with the size of the dimension in each index.
Passing a struct by field names

This example illustrates how to read various-type struct entries from MATLAB, and pass it to C equivalent type variables.

While it is possible and easy to figure out from the example how to load fields by numbers, it is here achieved via comparing the field names to strings. Thus the struct fields can be addressed by their field names and variables in it can be read by C.

**structIn.c**

```c
#include "mex.h"
#include <string.h> // strcmp

void mexFunction (int nlhs, mxArray *plhs[],
  int nrhs, const mxArray *prhs[])
{
  // helpers
  double* double_ptr;
  unsigned int i; // loop variable

  // to be read variables
  bool optimal;
  int randomseed;
  unsigned int desiredNodes;

  if (!mxIsStruct(prhs[0])) {
    mexErrMsgTxt("First argument has to be a parameter struct!");
  }
  for (i=0; i<mxGetNumberOfFields(prhs[0]); i++) {
    if (0==strcmp(mxGetFieldNameByNumber(prhs[0],i),"randomseed")) {
      mxArray *p = mxGetFieldByNumber(prhs[0],0,i);
      randomseed = *mxGetPr(p);
    }
    if (0==strcmp(mxGetFieldNameByNumber(prhs[0],i),"optimal")) {
      mxArray *p = mxGetFieldByNumber(prhs[0],0,i);
      optimal = (bool)*mxGetPr(p);
    }
    if (0==strcmp(mxGetFieldNameByNumber(prhs[0],i),"numNodes")) {
      mxArray *p = mxGetFieldByNumber(prhs[0],0,i);
      desiredNodes = *mxGetPr(p);
    }
  }
}
```

The loop over i runs over every field in the given struct, while the if(0==strcmp) parts compare the matlab field's name to the given string. If it is a match, the corresponding value is extracted to a C variable.

Chapter 19: MATLAB Best Practices

Remarks

This topic displays best practices that the community has learned over time.

Examples

Keep lines short

Use the continuation character (ellipsis) ... to continue long statement.

Example:

MyFunc( parameter1, parameter2, parameter3, parameter4, parameter5, parameter6, parameter7, parameter8, parameter9)

can be replaced by:

MyFunc( parameter1, ...
       parameter2, ...
       parameter3, ...
       parameter4, ...
       parameter5, ...
       parameter6, ...
       parameter7, ...
       parameter8, ...
       parameter9)

Indent code properly

Proper indentation gives not only the aesthetic look but also increases the readability of the code.

For example, consider the following code:

% no need to understand the code, just give it a look
n = 2;
bf = false;
while n>1
   for ii = 1:n
      for jj = 1:n
         if ii+jj>30
            bf = true;
            break
         end
      end
   end
   if bf
      break
   end
end
if bf
break
end
n = n + 1;
end

As you can see, you need to give a careful look to see which loop and if statements are ending where.
With smart indentation, you'll get this look:

n = 2;
bf = false;
while n>1
    for ii = 1:n
        for jj = 1:n
            if ii+jj>30
                bf = true;
                break
            end
        end
        if bf
            break
        end
    end
    if bf
        break
    end
    n = n + 1;
end

This clearly indicates the starting and ending of loops/if statement.

You can do smart indentation by:
• selecting all your code (Ctrl+A)
• and then pressing Ctrl+I or clicking from edit bar.

Use assert

Matlab allows some very trivial mistakes to go by silently, which might cause an error to be raised much later in the run - making debugging hard. If you assume something about your variables, validate it.

function out1 = get_cell_value_at_index(scalar1,cell2)
    assert(isscalar(scalar1),'1st input must be a scalar')
    assert(iscell(cell2),'2nd input must be a cell array')

https://riptutorial.com/
Avoid loops

Most of the time, loops are computationally expensive with Matlab. Your code will be orders of magnitudes faster if you use vectorization. It also often makes your code more modular, easily modifiable, and easier to debug. The major downside is that you have to take time to plan the data structures, and dimension errors are easier to come by.

Examples

Don't write

```matlab
for t=0:0.1:2*pi
    R(end+1)=cos(t);
end
```

but

```matlab
t=0:0.1:2*pi;
R=cos(t)
```

Don't write

```matlab
for i=1:n
    for j=1:m
        c(i,j)=a(i)+2*b(j);
    end
end
```

But something similar to

```matlab
c=repmat(a.',1,m)+2*repmat(b,n,1)
```

For more details, see vectorization

Create Unique Name for Temporary File

While coding a script or a function, it can be the case that one or more than one temporary file be needed in order to, for example, store some data.

In order to avoid overwriting an existing file or to shadow a MATLAB function the `tempname` function can be used to generate a unique name for a temporary file in the system temporary
The filename is generated without the extension; it can be added by concatenating the desired extension to the name generated by `tempname`.

```matlab
my_temp_file_with_ext=[tempname '.txt']
```

The location of the system temporary folder can be retrieved by calling the `tempdir` function.

If, during the execution of the function/script, the temporary file is no longer needed, it can be deleted by using the function `delete`.

Since `delete` does not ask for confirmation, it might be useful to set `on` the option to move the file to be deleted in the `recycle` folder.

This can be done by using the function `recycle` this way:

```matlab
recycle('on')
```

In the following example, a possible usage of the functions `tempname`, `delete` and `recycle` is proposed.

```matlab
theta=0:.1:2*pi;
x=cos(theta);
y=sin(theta);

my_temp_file=[tempname '.mat']

[tmp_file_path,tmp_file_name,tmp_file_ext]=fileparts(my_temp_file)
uiwait(msgbox(sprintf('Path= %s
Name= %s
Ext= %s', tmp_file_path,tmp_file_name,tmp_file_ext),'TEMPORARY FILE'))

save(my_temp_file,'x','y','theta')
load(my_temp_file)
recycle('on')
```

https://riptutorial.com/
delete(my_temp_file)

Caveat

The temporary filename is generated by using the `java.util.UUID.randomUUID` method (randomUUID).

If MATLAB is run without JVM, the temporary filename is generated by using `matlab.internal.timing.timing` based on the CPU counter and time. In this case the temporary filename is not guaranteed to be unique.

Use validateattributes

The function `validateattributes` can be used to validate an array against a set of specifications. It can be therefore used to validate the input provided to a function.

In the following example, the function `test_validateattributes` requires three input:

```matlab
function test_validateattributes(input_1,input_2,input_3)

The input specification are:

- **array_1**:
  - class: double
  - size: [3,2]
  - values: elements must be not NaN

- **char_array**:
  - class: char
  - value: the string must not be empty

- **array_3**
  - class: double
  - size: [5,1]
  - values: elements must be real

To validate the three input, the function `validateattributes` can be called with the following syntax:

```matlab
validateattributes(A,classes,attributes,funcName,varName,argIndex)
```

where:

- `A` is the array to be validated
- `classes` is the type of the array (e.g. single, double, logical)
- `attributes` are the attributes the input array has to match (e.g. [3,2], size to specify the size of the array, nonnan to specify that the array shall not have NaN values)
• **funcName**: is the name of the function in which the validation occurs. This argument is used in the generation of the error message (if any)
• **varName**: is the name of the array under validation. This argument is used in the generation of the error message (if any)
• **argIndex**: is the position of the input array in the list of input. This argument is used in the generation of the error message (if any)

In case one or more than one input does not match the specification, an error message is generated.

In case of more than one invalid input, the validation stops when the first mismatch is found.

This is **function test_validateattributes** in which the input validation has been implemented.

Since the function requires three input, a first check on the number of input provided is performed using the function **nargin**.

```matlab
function test_validateattributes(array_1,char_array_1,array_3)

% Check for the number of expected input: if the number of input is less
% than the require, the function exits with an error message
% if(nargin ~= 3)
  error('Error: TEST_VALIDATEATTRIBUTES requires 3 input, found %d',nargin)
end

 %%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%
 % Definition of the expected characteristics of the first input
 %%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%%

 % INPUT #1 name (only used in the generation of the error message)
 input_1_name='array_1';
 % INPUT #1 position (only used in the generation of the error message)
 input_1_position=1;
 % Expected CLASS of the first input MUST BE "double"
 input_1_class={'double'};
 % Expected ATTRIBUTES of the first input
 % SIZE: MUST BE [3,2]
 input_1_size_attribute='size';
 input_1_size=[3,2];
 % VALUE CHECK: the element MUST BE NOT NaN
 input_1_value_type='nonnan';
 % Build the INPUT 1 attributes
 input_1_attributes={input_1_size_attribute,input_1_size, ... input_1_value_type};
```

https://riptutorial.com/
% CHECK THE VALIDITY OF THE FIRST INPUT

validateattributes(array_1, ...
input_1_class,input_1_attributes,'', ...
input_1_name,input_1_position);

% Definition of the expected characteristics of the second input %

% INPUT #1 name (only used in the generation of the error message)
input_2_name='char_array_1';

% INPUT #2 position (only used in the generation of the error message)
input_2_position=2;

% Expected CLASS of the first input MUST BE "string"
input_2_class={'char'};

% VALUE CHECK: the element must be not NaN
input_2_size_attribute='nonempty';

% Build the INPUT 2 attributes
input_2_attributes={input_2_size_attribute};

% CHECK THE VALIDITY OF THE SECOND INPUT

validateattributes(char_array_1, ...
input_2_class,input_2_attributes,'', ...
input_2_name,input_2_position);

% Definition of the expected characteristics of the third input %

% INPUT #3 name (only used in the generation of the error message)
input_3_name='array_3';

% INPUT #3 position (only used in the generation of the error message)
input_3_position=3;

% Expected CLASS of the first input MUST BE "double"
input_3_class={'double'};

% Expected ATTRIBUTES of the first input
% SIZE: must be [5]
input_3_size_attribute='size';
input_3_size=[5 1];
% VALUE CHECK: the elements must be real
input_3_value_type='real';

% Build the INPUT 3 attributes
\[
\text{input}_3_\text{attributes} = \{\text{input}_3_\text{size_attribute}, \text{input}_3_\text{size}, \ldots
\quad\text{input}_3_\text{value_type}\};
\]

% CHECK THE VALIDITY OF THE FIRST INPUT
% validateattributes(array_3, ...\n% input_3_class, input_3_attributes, \\
% input_3_name, input_3_position);

disp('All the three input are OK')

The following script can be used to test the implementation of the validation procedure.

It generate the three input required and, randomly, it makes them not valid.

\[
\%
% Generate the first input
% \n% n_rows = randi([2 3],1);
% n_cols = 2;
% input_1 = randi([20 30], n_rows, n_cols);
% \%
% Generate the second input
% if(rand > 0.5)
%    input_2 = 'This is a string';
% else
%    input_2 = '';
% end
% \%
% Generate the third input
% input_3 = acos(rand(5,1)*1.2);
% \%
% Call the test_validateattributes function with the above generated input
% \n% input_1
% input_2
% input_3
% test_validateattributes(input_1, input_2, input_3)
\]

These are a couple of examples of wrong input detected by the \texttt{validateattributes} function:

Wrong input

\[
\text{input}_1 = \\
\begin{array}{cc}
23 & 22 \\
26 & 28 \\
\end{array}
\]

\[
\text{input}_2 = \\
'
\]

\[
\text{input}_3 =
\]
Error using test_validateattributes (line 44)
Expected input number 1, array_1, to be of size 3x2 when it is actually size 2x2.

Wrong input

input_1 =

22  24
21  25
26  27

input_2 =

This is a string

input_3 =

1.1371 + 0.0000i
0.6528 + 0.0000i
1.0479 + 0.0000i
0.0000 + 0.1435i
0.0316 + 0.0000i

Error using test_validateattributes (line 109)
Expected input number 3, array_3, to be real.

Valid input

input_1 =

20  25
25  28
24  23

input_2 =

This is a string

input_3 =

0.9696
1.5279
1.3581
0.5234
0.9665

All the three input are OK
It is a good practice to add comments that describe the code. It is helpful for others and even for the coder when returned later. A single line can be commented using the `%` symbol or using the shortkey Ctrl+R. To uncomment a previously commented line remove the `%` symbol or use shortkey Ctrl+T.

While commenting a block of code can be done by adding a `%` symbol at the beginning of each line, newer versions of MATLAB (after 2015a) let you use the **Block Comment Operator** ` %{ code %}`. This operator increases the readability of the code. It can be used for both code commenting and function help documentation. The Block can be **folded** and **unfolded** to increase the readability of the code.

```matlab
function y = myFunction(x)
%{
    myFunction  Binary Singleton Expansion Function
    y = myFunction(x) applies the element-by-element binary operation
    specified by the function handle FUNC to arrays A and B, with implicit
    expansion enabled.
%}

    % Compute z(x, y) = x.*sin(y) on a grid:
    % x = 1:10;
    y = x.';

    %{ 
    z = zeros(numel(x),numel(y));
    for ii=1:numel(x)
        for jj=1:numel(y)
            z(ii,jj) = x(ii)*sin(y(jj));
        end
    end
    %{
    z = bsxfun(@times, x, y);
    y = y + z;

end
```

As it can be seen the ` %{ code %}` operators must appear alone on the lines. Do not include any other text on these lines.
expansion enabled.
%

%% Compute \( z(x, y) = x \cdot \sin(y) \) on a grid:

\[
\begin{align*}
x & = 1:10; \\
y & = x.'; \\
\end{align*}
\]

\[
\begin{align*}
\{ \\
z & = \text{zeros}(\text{numel}(x), \text{numel}(y)); \\
\text{for} & \ ii=1:\text{numel}(x) \\
& \quad \text{for} \ jj=1:\text{numel}(y) \\
& \quad \quad z(ii,jj) = x(ii) \cdot \sin(y(jj)); \\
& \quad \end{align*}
\]

end

end

\{ \\
z & = \text{bsxfun}(\text{@}(x, y) \ x \cdot \sin(y), x, y); \\
y & = y + z; \\
end

---

Chapter 20: MATLAB User Interfaces

Examples

Passing Data Around User Interface

Most advanced user interfaces require the user to be able to pass information between the various functions which make up a user interface. MATLAB has a number of different methods to do so.

**guidata**

MATLAB's own GUI Development Environment (GUIDE) prefers to use a struct named handles to pass data between callbacks. This struct contains all of the graphics handles to the various UI components as well as user-specified data. If you aren't using a GUIDE-created callback which automatically passes handles, you can retrieve the current value using guidata

```matlab
% hObject is a graphics handle to any UI component in your GUI
handles = guidata(hObject);
```

If you want to modify a value stored in this data structure, you can modify but then you must store it back within the hObject for the changes to be visible by other callbacks. You can store it by specifying a second input argument to guidata.

```matlab
% Update the value
handles.myValue = 2;

% Save changes
guidata(hObject, handles)
```

The value of hObject doesn't matter as long as it is a UI component within the same figure because ultimately the data is stored within the figure containing hObject.

**Best for:**

- Storing the handles structure, in which you can store all the handles of your GUI components.
- Storing "small" other variables which need to be accessed by most callbacks.

**Not recommended for:**

- Storing large variables which do not have to be accessed by all callbacks and sub-functions (use setappdata/getappdata for these).

**setappdata/getappdata**
Similar to the `guidata` approach, you can use `setappdata` and `getappdata` to store and retrieve values from within a graphics handle. The advantage of using these methods is that you can retrieve *only the value you want* rather than an entire `struct` containing *all* stored data. It is similar to a key/value store.

**To store data within a graphics object**

```matlab
% Create some data you would like to store
myvalue = 2

% Store it using the key 'mykey'
setappdata(hObject, 'mykey', myvalue)
```

And to retrieve that same value from within a different callback

```matlab
value = getappdata(hObject, 'mykey');
```

**Note:** If no value was stored prior to calling `getappdata`, it will return an empty array `([],[])`.

Similar to `guidata`, the data is stored in the figure that contains `hObject`.

**Best for:**

- Storing large variables which do not have to be accessed by all callbacks and sub-functions.

---

**UserData**

Every graphics handle has a special property, `UserData` which can contain any data you wish. It could contain a cell array, a `struct`, or even a scalar. You can take advantage of this property and store any data you wish to be associated with a given graphics handle in this field. You can save and retrieve the value using the standard `get/set` methods for graphics objects or dot notation if you're using R2014b or newer.

```matlab
% Create some data to store
mydata = {1, 2, 3};

% Store it within the UserData property
set(hObject, 'UserData', mydata)

% Of if you're using R2014b or newer:
% hObject.UserData = mydata;
```

Then from within another callback, you can retrieve this data:

```matlab
their_data = get(hObject, 'UserData');

% Or if you're using R2014b or newer:
% their_data = hObject.UserData;
```

**Best for:**

https://riptutorial.com/
• Storing variables with a limited scope (variables which are likely to be used only by the object in which they are stored, or objects having a direct relationship to it).

---

### Nested Functions

In MATLAB, a nested function can read and modify any variable defined in the parent function. In this way, if you specify a callback to be a nested function, it can retrieve and modify any data stored in the main function.

```matlab
function mygui()
    hButton = uicontrol('String', 'Click Me', 'Callback', @callback);

    % Create a counter to keep track of the number of times the button is clicked
    nClicks = 0;

    % Callback function is nested and can therefore read and modify nClicks
    function callback(source, event)
        % Increment the number of clicks
        nClicks = nClicks + 1;

        % Print the number of clicks so far
        fprintf('Number of clicks: %d
', nClicks);
    end
end
```

**Best for:**

- Small, simple GUIs. (for quick prototyping, to not have to implement the `guidata` and/or `set/getappdata` methods).

**Not recommended for:**

- Medium, large or complex GUIs.
- GUI created with GUIDE.

---

### Explicit input arguments

If you need to send data to a callback function and don't need to modify the data within the callback, you can always consider passing the data to the callback using a carefully crafted callback definition.

You could use an anonymous function which adds inputs

```matlab
% Create some data to send to mycallback
data = [1, 2, 3];

% Pass data as a third input to mycallback
```
Or you could use the cell array syntax to specify a callback, again specifying additional inputs.

```matlab
set(hObject, 'Callback', {@mycallback, data})
```

**Best for:**

- When the callback needs `data` to perform some operations but the `data` variable does not need to be modified and saved in a new state.

### Making a button in your UI that pauses callback execution

Sometimes we'd like to pause code execution to inspect the state of the application (see [Debugging](#)). When running code through the MATLAB editor, this can be done using the "Pause" button in the UI or by pressing `Ctrl+c` (on Windows). However, when a computation was initiated from a GUI (via the callback of some `uicontrol`), this method does not work anymore, and the callback should be interrupted via another callback. Below is a demonstration of this principle:

```matlab
function interruptibleUI
dbclear in interruptibleUI % reset breakpoints in this file
figure('Position', [400,500,329,160]);
uicontrol('Style', 'pushbutton', ...  
  'String', 'Compute', ...  
  'Position', [24 55 131 63], ...  
  'Callback', @longComputation, ...  
  'Interruptible', 'on'); % 'on' by default anyway

uicontrol('Style', 'pushbutton', ...  
  'String', 'Pause #1', ...  
  'Position', [180 87 131 63], ...  
  'Callback', @interrupt1);

uicontrol('Style', 'pushbutton', ...  
  'String', 'Pause #2', ...  
  'Position', [180 12 131 63], ...  
  'Callback', @interrupt2);
end

function longComputation(src, event)
  superSecretVar = rand(1);
  pause(15);
  print('done!'); % we'll use this to determine if code kept running "in the background".
end

function interrupt1(src, event) % depending on where you want to stop
  dbstop in interruptibleUI at 27 % will stop after print('done!');
  dbstop in interruptibleUI at 32 % will stop after **this** line.
end

function interrupt2(src, event) % method 2
  keyboard;
```
To make sure you understand this example do the following:

1. Paste the above code into a new file called and save it as interruptibleUI.m, such that the code starts on the very first line of the file (this is important for the 1st method to work).
2. Run the script.
3. Click Compute and shortly afterwards click either Pause #1 or on Pause #2.
4. Make sure you can find the value of superSecretVar.

**Passing data around using the "handles" structure**

This is an example of a basic GUI with two buttons that change a value stored in the GUI’s handles structure.

```matlab
function gui_passing_data() % A basic GUI with two buttons to show a simple use of the 'handles' % structure in GUI building
    % Create a new figure.
    f = figure();
    % Retrieve the handles structure
    handles = guidata(f);
    % Store the figure handle
    handles.figure = f;
    % Create an edit box and two buttons (plus and minus), % and store their handles for future use
    handles.hedit = uicontrol('Style','edit','Position',[10,200,60,20], 'Enable','Inactive');
    handles.hbutton_plus = uicontrol('Style','pushbutton','String','+',... 'Position',[80,200,60,20], 'Callback', @ButtonPress);
    handles.hbutton_minus = uicontrol('Style','pushbutton','String','-',... 'Position',[150,200,60,20], 'Callback', @ButtonPress);
    % Define an initial value, store it in the handles structure and show % it in the Edit box
    handles.value = 1;
    set(handles.hedit, 'String', num2str(handles.value))
    % Store handles
    guidata(f, handles);
end
```

```matlab
function ButtonPress(hObject, eventdata) % A button was pressed % Retrieve the handles
    handles = guidata(hObject);
    % Determine which button was pressed; hObject is the calling object
    switch(get(hObject, 'String'))
```
case '+'
    % Add 1 to the value
    handles.value = handles.value + 1;
    set(handles.hedit , 'String', num2str(handles.value))
  case '-'
    % Subtract 1 from the value
    handles.value = handles.value - 1;
  end

  % Display the new value
  set(handles.hedit , 'String', num2str(handles.value))

  % Store handles
  guidata(hObject, handles);

To test the example, save it in a file called `gui_passing_data.m` and launch it with F5. Please note that in such a simple case, you would not even need to store the value in the handles structure because you could directly access it from the edit box's `String` property.

Performance Issues when Passing Data Around User Interface

Two main techniques allow passing data between GUI functions and Callbacks: `setappdata/getappdata` and `guidata` (read more about it). The former should be used for larger variables as it is more time efficient. The following example tests the two methods' efficiency.

A GUI with a simple button is created and a large variable (10000x10000 double) is stored both with `guidata` and with `setappdata`. The button reloads and stores back the variable using the two methods while timing their execution. The running time and percentage improvement using `setappdata` are displayed in the command window.

```matlab
function gui_passing_data_performance()
    % A basic GUI with a button to show performance difference between
    % guidata and setappdata
    % Create a new figure.
    f = figure('Units' , 'normalized');

    % Retrieve the handles structure
    handles = guidata(f);

    % Store the figure handle
    handles.figure = f;

    % Create an uninteresting large array
    data = zeros(10000);

    % Store it in appdata
    setappdata(handles.figure , 'data' , data);

    % Store it in handles
    handles.data = data;
```
% Save handles
guidata(f, handles);

function  ButtonPress(hObject, eventdata)
    % Calculate the time difference when using guidata and appdata
    t_handles = timeit(@use_handles);
    t_appdata = timeit(@use_appdata);

    % Absolute and percentage difference
    t_diff = t_handles - t_appdata;
    t_perc = round(t_diff / t_handles * 100);

    disp(['Difference: ' num2str(t_diff) ' ms / ' num2str(t_perc) '%'])

function  use_appdata()
    % Retrieve the data from appdata
    data = getappdata(gcf, 'data');

    % Do something with data %
    % Store the value again
    setappdata(gcf, 'data', data);

function use_handles()
    % Retrieve the data from handles
    handles = guidata(gcf);
    data = handles.data;

    % Do something with data %
    % Store it back in the handles
    handles.data = data;
    guidata(gcf, handles);

On my Xeon W3530@2.80 GHz I get \textbf{Difference: 0.00018957 ms / 73 \%}, thus using getappdata/setappdata I get a performance improvement of 73\%! Note that the result does not change if a 10x10 double variable is used, however, result will change if handles contains many fields with large data.

Chapter 21: Matrix decompositions

Syntax

1. \( R = \text{chol}(A); \)
2. \([L,U] = \text{lu}(A);\)
3. \( R = \text{qr}(A); \)
4. \( T = \text{schur}(A); \)
5. \([U,S,V] = \text{svd}(A); \)

Examples

Cholesky decomposition

The Cholesky decomposition is a method to decompose an hermitean, positiv definite matrix into an upper triangular matrix and its transpose. It can be used to solve linear equations systems and is around twice as fast as LU-decomposition.

\[
A = \begin{bmatrix}
4 & 12 & -16 \\
12 & 37 & -43 \\
-16 & -43 & 98 \\
\end{bmatrix};
\]

\( R = \text{chol}(A); \)

This returns the upper triangular matrix. The lower one is obtained by transposition.

\( L = R'; \)

We finally can check whether the decomposition was correct.

\( b = (A == L*R); \)

QR decomposition

This method will decompose a matrix into an upper triangular and an orthogonal matrix.

\[
A = \begin{bmatrix}
4 & 12 & -16 \\
12 & 37 & -43 \\
-16 & -43 & 98 \\
\end{bmatrix};
\]

\( R = \text{qr}(A); \)

This will return the upper triangular matrix while the following will return both matrices.

\( [Q,R] = \text{qr}(A); \)

The following plot will display the runtime of \( \text{qr} \) dependent of the square root of elements of the
**LU decomposition**

Hereby a matrix will be decomposed into an upper triangular and an lower triangular matrix. Often it will be used to increase the performance and stability (if it's done with permutation) of Gauß elimination.

However, quite often does this method not or badly work as it is not stable. For example

```matlab
A = [8 1 6
     3 5 7
     4 9 2];
[L,U] = lu(A);
```

It is sufficient to add an permutation matrix such that PA=LU:

```matlab
[L,U,P]=lu(A);
```

In the following we will now plot the runtime of `lu` dependent of the square root of elements of the matrix.
Schur decomposition

If \( A \) is a complex and quadratic matrix there exists a unitary \( Q \) such that \( Q^*AQ = T = D + N \) with \( D \) being the diagonal matrix consisting of the eigenvalues and \( N \) being strictly upper tridiagonal.

\[
A = \begin{bmatrix}
3 & 6 & 1 \\
23 & 13 & 1 \\
0 & 3 & 4
\end{bmatrix};
\]

\[
T = \text{schur}(A);
\]

We also display the runtime of \texttt{schur} dependent on the square root of matrix elements:
Singular value decomposition

Given an m times n matrix A with n larger than m. The singular value decomposition

\[ [U, S, V] = \text{svd}(A); \]

computes the matrices U,S,V.

The matrix U consists of the left singular eigenvectors which are the eigenvectors of \( A^* A \) \( \text{while V} \) consists of the right singular eigenvalues which are the eigenvectors of \( A^* A \). The matrix S has the square roots of the eigenvalues of \( A^* A \) on its diagonal.

If m is larger than n one can use

\[ [U, S, V] = \text{svd}(A, 'econ'); \]

to perform economy sized singular value decomposition.

Read Matrix decompositions online: https://riptutorial.com/matlab/topic/6163/matrix-decompositions
Chapter 22: Multithreading

Examples

Using parfor to parallelize a loop

You can use `parfor` to execute the iterations of a loop in parallel:

Example:

```matlab
poolobj = parpool(2);       % Open a parallel pool with 2 workers
s = 0;                      % Performing some parallel Computations
parfor i=0:9
    s = s + 1;
end
disp(s)                     % Outputs '10'
delete(poolobj);            % Close the parallel pool
```

Note: `parfor` cannot be nested directly. For `parfor` nesting use a function in first `parfor` and add second `parfor` in that function.

Example:

```matlab
parfor i = 1:n
    [op] = fun_name(ip);
end

function [op] = fun_name(ip)
    parfor j = 1:length(ip)
        % Some Computation
    end
end
```

When to use parfor

Basically, `parfor` is recommended in two cases: lots of iterations in your loop (i.e., like `1e10`), or if each iteration takes a very long time (e.g., `eig(magic(1e4)`). In the second case you might want to consider using `spmd`. The reason `parfor` is slower than a `for` loop for short ranges or fast iterations is the overhead needed to manage all workers correctly, as opposed to just doing the calculation.

Also a lot of functions have implicit multi-threading built-in, making a `parfor` loop not more efficient, when using these functions, than a serial `for` loop, since all cores are already being used. `parfor` will actually be a detriment in this case, since it has the allocation overhead, whilst being as parallel as the function you are trying to use.

Consider the following example to see the behaviour of `for` as opposed to that of `parfor`. First open the parallel pool if you’ve not already done so:
gcp; % Opens a parallel pool using your current settings

Then execute a couple of large loops:

```
n = 1000; % Iteration number
EigenValues = cell(n,1); % Prepare to store the data
Time = zeros(n,1);
for ii = 1:n
    tic
    EigenValues{ii,1} = eig(magic(1e3)); % Might want to lower the magic if it takes too long
    Time(ii,1) = toc; % Collect time after each iteration
end

figure; % Create a plot of results
plot(1:n,t)
title 'Time per iteration'
ylabel 'Time [s]'
xlabel 'Iteration number[-]';
```

Then do the same with `parfor` instead of `for`. You will notice that the average time per iteration goes up. Do realise however that the `parfor` used all available workers, thus the total time (`sum(Time)`) has to be divided by the number of cores in your computer.

So, whilst the time to do each separate iteration goes up using `parfor` with respect to using `for`, the total time goes down considerably.

**Executing commands in parallel using a "Single Program, Multiple Data" (SPMD) statement**

Unlike a parallel for-loop (`parfor`), which takes the iterations of a loop and distributes them among multiple threads, a single program, multiple data (`spmd`) statement takes a series of commands and distributes them to all the threads, so that each thread performs the command and stores the results. Consider this:

```
poolobj = parpool(2); % open a parallel pool with two workers

spmd
    q = rand(3); % each thread generates a unique 3x3 array of random numbers
end

q{1} % q is called like a cell vector
q{2} % the values stored in each thread may be accessed by their index

delete(poolobj) % if the pool is closed, then the data in q will no longer be accessible
```

It is important to note that each thread may be accessed during the `spmd` block by its thread index (also called `labindex`):

```
poolobj = parpool(2); % open a parallel pool with two workers

spmd
    q = rand(labindex + 1); % each thread generates a unique array of random numbers
end
```
In both examples, \( q \) is a **composite object**, which may be initialized with the command \( q = \text{Composite()} \). It is important to note that composite objects are only accessible while the pool is running.

### Using the batch command to do various computations in parallel

To use multi-threading in MATLAB one can use the `batch` command. Note that you must have the Parallel Computing toolbox installed.

For a time-consuming script, for example,

```matlab
for ii=1:1e8
    A(ii)=sin(ii*2*pi/1e8);
end
```

to run it in batch mode one would use the following:

```matlab
job=batch("da")
```

which is enables MATLAB to run in batch mode and makes it possible to use MATLAB in the meantime to do other things, such as add more batch processes.

To retrieve the results after finishing the job and load the array \( A \) into the workspace:

```matlab
load(job, 'A')
```

Finally, open the "monitor job gui" from Home → Environment → Parallel → Monitor jobs and delete the job through:

```matlab
delete(job)
```

To load a function for batch processing, simply use this statement where \( fcn \) is the function name, \( N \) is number of output arrays and \( x_1, \ldots, x_n \) are input arrays:

```matlab
j=batch(fcn, N, {x1, x2, ..., xn})
```

</tr>
<tr>
<td><code>delete(poolobj)</code></td>
<td>% q is no longer accessible</td>
</tr>
</tbody>
</table>
Chapter 23: Object-Oriented Programming

Examples

Defining a class

A class can be defined using `classdef` in an `.m` file with the same name as the class. The file can contain the `classdef...end` block and local functions for use within class methods.

The most general MATLAB class definition has the following structure:

```matlab
classdef (ClassAttribute = expression, ...) ClassName < ParentClass1 & ParentClass2 & ...

  properties (PropertyAttributes)
    PropertyName
  end

  methods (MethodAttributes)
    function obj = methodName(obj,arg2,...)
      ...
    end
  end

  events (EventAttributes)
    EventName
  end

  enumeration
    EnumName
  end

end
```

MATLAB Documentation: Class attributes, Property attributes, Method attributes, Event attributes, Enumeration class restrictions.

Example class:

A class called `Car` can be defined in file `Car.m` as

```matlab
classdef Car < handle % handle class so properties persist
  properties
    make
    model
    mileage = 0;
  end

  methods
    function obj = Car(make, model)
      obj.make = make;
      obj.model = model;
    end

    function drive(obj, milesDriven)
  end
```

https://riptutorial.com/
Note that the constructor is a method with the same name as the class. A constructor is a special method of a class or structure in object-oriented programming that initializes an object of that type. A constructor is an instance method that usually has the same name as the class, and can be used to set the values of the members of an object, either to default or to user-defined values.

An instance of this class can be created by calling the constructor:

```matlab
>> myCar = Car('Ford', 'Mustang'); //creating an instance of car class
```

Calling the `drive` method will increment the mileage

```matlab
>> myCar.mileage
ans =
 0
>> myCar.drive(450);
>> myCar.mileage
ans =
450
```

### Value vs Handle classes

Classes in MATLAB are divided into two major categories: value classes and handle classes. The major difference is that when copying an instance of a value class, the underlying data is copied to the new instance, while for handle classes the new instance points to the original data and changing values in new instance changes them in the original. A class can be defined as a handle by inheriting from the `handle` class.

```matlab
classdef valueClass
    properties
        data
    end
end
```

and

```matlab
classdef handleClass < handle
    properties
        data
    end
end
```

then
Inheriting from classes and abstract classes

Disclaimer: the examples presented here are only for the purpose of showing the use of abstract classes and inheritance and may not necessarily be of a practical use. Also, there is no such thing as polymorphic in MATLAB and therefore the use of abstract classes is limited. This example is to show how to create a class, inherit from another class and apply an abstract class to define a common interface.

The use of abstract classes is rather limited in MATLAB but it still can come useful on a couple of occasions.

Let's say we want a message logger. We might create a class similar to the one below:

```matlab
classdef ScreenLogger
    properties(Access=protected)
        scrh;
    end

    methods
        function obj = ScreenLogger(screenhandler)
            obj.scrh = screenhandler;
        end

        function LogMessage(obj, varargin)
            if ~isempty(varargin)
                varargin{1} = num2str(varargin{1});
                fprintf(obj.scrh, '%s\n', sprintf(varargin{:}));
            end
        end
    end
end
```

Properties and methods

In short, properties hold a state of an object whilst methods are like interface and define actions on objects.

The property `scrh` is protected. This is why it must be initialized in a constructor. There are other methods (getters) to access this property but it is out of scope of this example.
methods can be access via a variable that holds a reference to an object by using dot notation followed by a name of a method or a property:

```matlab
mylogger = ScreenLogger(1);                         % OK
mylogger.LogMessage('My %s %d message', 'very', 1); % OK
mylogger.scrh = 2;                                  % ERRR!!! Access denied
```

Properties and methods can be public, private, or protected. In this case, protected means that I will be able to access to `scrh` from an inherited class but not from outside. By default all properties and methods are public. Therefore `LogMessage()` can freely be used outside the class definition. Also `LogMessage` defines an interface meaning this is what we must call when we want an object to log our custom messages.

**Application**

Let's say I have a script where I utilize my logger:

```matlab
clc;
% ... a code
logger = ScreenLogger(1);
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
```

If I have multiple places where I use the same logger and then want to change it to something more sophisticated, such as write a message in a file, I would have to create another object:

```matlab
classdef DeepLogger
    properties(SetAccess=protected)
        FileName
    end
    methods
        function obj = DeepLogger(filename)
            obj.FileName = filename;
        end
        function LogMessage(obj, varargin)
            if ~isempty(varargin)
                varargin{1} = num2str(varargin{1});
                fid = fopen(obj.fullfname, 'a+t');
                fprintf(fid, '%s
', sprintf(varargin{:}));
                fclose(fid);
            end
        end
    end
end
```

and just change one line of a code into this:
The above method will simply open a file, append a message at the end of the file and close it. At the moment, to be consistent with my interface, I need to remember that the name of a method is LogMessage() but it could equally be anything else. MATLAB can force developer to stick to the same name by using abstract classes. Let’s say we define a common interface for any logger:

```matlab
classdef MessageLogger
    methods(Abstract=true)
        LogMessage(obj, varargin);
    end
end
```

Now, if both ScreenLogger and DeepLogger inherit from this class, MATLAB will generate an error if LogMessage() is not defined. Abstract classes help to build similar classes which can use the same interface.

For the sake of this example, I will make slightly different change. I am going to assume that DeepLogger will do both logging message on a screen and in a file at the same time. Because ScreenLogger already log messages on screen, I am going to inherit DeepLogger from the ScreenLogger to avoid repetition. ScreenLogger doesn’t change at all apart from the first line:

```matlab
classdef ScreenLogger < MessageLogger
    // the rest of previous code
```

However, DeepLogger needs more changes in the LogMessage method:

```matlab
classdef DeepLogger < MessageLogger & ScreenLogger
    properties(SetAccess=protected)
        FileName
        Path
    end
    methods
        function obj = DeepLogger(screenhandler, filename)
            [path,filen,ext] = fileparts(filename);
            obj.FileName = [filen ext];
            pbj.Path = pathn;
            obj = obj@ScreenLogger(screenhandler);
        end
        function LogMessage(obj, varargin)
            if ~isempty(varargin)
                varargin{1} = num2str(varargin{1});
                LogMessage@ScreenLogger(obj, varargin{:});
                fid = fopen(obj.fullfname, 'a+t');
                fprintf(fid, '%s
', sprintf(varargin{:}));
                fclose(fid);
            end
        end
    end
end
```

Firstly, I simply initialize properties in the constructor. Secondly, because this class inherits from
I have to initialize this parrent object as well. This line is even more important because `ScreenLogger` constructor requires one parameter to initialize its own object. This line:

```
obj = obj@ScreenLogger(screenhandler);
```

simply says "call the constructor of `ScreenLogger` and initialize it with a screen handler". It is worth noting here that I have defined `scrh` as protected. Therefore, I could equally access this property from `DeepLogger`. If the property was defined as private. The only way to initialize it would be using constructor.

Another change is in section methods. Again to avoid repetition, I call `LogMessage()` from a parent class to log a message on a screen. If I had to change anything to make improvements in screen logging, now I have to do it in one place. The rest code is the same as it is a part of `DeepLogger`.

Because this class also inherits from an abstract class `MessageLogger` I had to make sure that `LogMessage()` inside `DeepLogger` is also defined. Inheriting from `MessageLogger` is a little bit tricky here. I think it cases redefinition of `LogMessage` mandatory--my guess.

In terms of the code where the a logger is applied, thanks to a common interface in classes, I can rest assure there changin this one line in the whole code would not make any issues. The same messages will be log on screen as before but additionally the code will write such messages to a file.

```
clc;
% ... a code
logger = DeepLogger(1, 'mylogfile.log');
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
% ... a code
logger.LogMessage('something');
```

I hope these examples explained the use of classes, the use of inheritance, and the use of abstract classes.

---

PS. The solution for the above problem is one of many. Another solution, less complex, would be to make `ScreenLogger` to be a component of another logger like `FileLogger` etc. `ScreenLogger` would be held in one of the properties. Its `LogMessage` would simply call `LogMessage` of the `ScreenLogger` and show text on a screen. I have chosen more complex approach to rather show how classes work in MATLAB. The example code below:

```
classdef DeepLogger < MessageLogger
    properties(SetAccess=protected)
        FileName
        Path
        ScrLogger
    end
```
methods
    function obj = DeepLogger(screenhandler, filename)
        [path,filen,ext] = fileparts(filename);
        obj.FileName   = [filen ext];
        obj.Path       = pathn;
        obj.ScrLogger  = ScreenLogger(screenhandler);
    end
    function LogMessage(obj, varargin)
        if ~isempty(varargin)
            varargin{1} = num2str(varargin{1});
            obj.LogMessage(obj.ScrLogger, varargin{:}); % <-------- the change here
            fid = fopen(obj.fullfname, 'a+t');
            fprintf(fid, '%s
', sprintf(varargin{:}));
            fclose(fid);
        end
    end
end

Constructors

A **constructor** is a special method in a class that is called when an instance of an object is created. It is a regular MATLAB function that accepts input parameters but it also must follow certain rules. Constructors are not required as MATLAB creates a default one. In practice, however, this is a place to define a state of an object. For example, properties can be restricted by specifying attributes. Then, a constructor can initialize such properties by default or user defined values which in fact can sent by input parameters of a constructor.

**Calling a constructor of a simple class**

This is a simple class **Person**.

```matlab
classdef Person
    properties
        name
        surname
        address
    end
    methods
        function obj = Person(name,surname,address)
            obj.name   = name;
            obj.surname = surname;
            obj.address = address;
        end
    end
end
```

The name of a constructor is the same the name of a class. Consequently, constructors are called by the name of its class. A class **Person** can be created as follows:

```matlab
>> p = Person('John','Smith','London')
p =
    Person with properties:
```
Calling a constructor of a child class

Classes can be inherited from parent classes if they share common properties or methods. When a class is inherited from another, it is likely that a constructor of a parent class has to be called.

A class `Member` inherits from a class `Person` because `Member` uses the same properties as the class `Person` but it also adds `payment` to its definition.

```matlab
classdef Member < Person
    properties
        payment
    end

    methods
        function obj = Member(name,surname,address,payment)
            obj = obj@Person(name,surname,address);
            obj.payment = payment;
        end
    end
end
```

Similarly to the class `Person`, `Member` is created by calling its constructor:

```matlab
>> m = Member('Adam','Woodcock','Manchester',20)
```

```
Member with properties:
    payment: 20
    name: 'Adam'
    surname: 'Woodcock'
    address: 'Manchester'
```

A constructor of `Person` requires three input parameters. `Member` must respect this fact and therefore call a constructor of the class `Person` with three parameters. It is fulfilled by the line:

```matlab
obj = obj@Person(name,surname,address);
```

The example above shows the case when a child class needs information for its parent class. This is why a constructor of `Member` requires four parameters: three for its parent class and one for itself.

Read Object-Oriented Programming online: https://riptutorial.com/matlab/topic/1028/object-oriented-programming
Chapter 24: Ordinary Differential Equations (ODE) Solvers

Examples

Example for odeset

First we initialize our initial value problem we want to solve.

```matlab
odefun = @(t,y) cos(y).^2*sin(t);
tspan = [0 16*pi];
y0=1;
```

We then use the ode45 function without any specified options to solve this problem. To compare it later we plot the trajectory.

```matlab
[t,y] = ode45(odefun, tspan, y0);
plot(t,y,'-o');
```

We now set a narrow relative and a narrow absolut limit of tolerance for our problem.

```matlab
options = odeset('RelTol',1e-2,'AbsTol',1e-2);
[t,y] = ode45(odefun, tspan, y0, options);
plot(t,y,'-o');
```

We set tight relative and narrow absolut limit of tolerance.

```matlab
options = odeset('RelTol',1e-7,'AbsTol',1e-2);
[t,y] = ode45(odefun, tspan, y0, options);
plot(t,y,'-o');
```

We set narrow relative and tight absolut limit of tolerance. As in the previous examples with narrow limits of tolerance one sees the trajectory being completely different from the first plot without any specific options.

```matlab
options = odeset('RelTol',1e-2,'AbsTol',1e-7);
[t,y] = ode45(odefun, tspan, y0, options);
plot(t,y,'-o');
```

We set tight relative and tight absolut limit of tolerance. Comparing the result with the other plot will underline the errors made calculating with narrow tolerance limits.

```matlab
options = odeset('RelTol',1e-7,'AbsTol',1e-7);
[t,y] = ode45(odefun, tspan, y0, options);
plot(t,y,'-o');
```
The following should demonstrate the trade-off between precision and run-time.

```matlab
tic;
options = odeset('RelTol',1e-7,'AbsTol',1e-7);
[t,y] = ode45(odefun, tspan, y0, options);
time1 = toc;
plot(t,y,'-o');
```

For comparison we tighten the limit of tolerance for absolute and relative error. We now can see that without large gain in precision it will take considerably longer to solve our initial value problem.

```matlab
tic;
options = odeset('RelTol',1e-13,'AbsTol',1e-13);
[t,y] = ode45(odefun, tspan, y0, options);
time2 = toc;
plot(t,y,'-o');
```

Read Ordinary Differential Equations (ODE) Solvers online:
Remarks

- Profiling code is a way to avoid the dreaded practice of "premature optimization", by focusing the developer on those parts of the code that actually justify optimization efforts.
- MATLAB documentation article titled "Measure Performance of Your Program".

Examples

Identifying performance bottlenecks using the Profiler

The MATLAB Profiler is a tool for software profiling of MATLAB code. Using the Profiler, it is possible to obtain a visual representation of both execution time and memory consumption.

Running the Profiler can be done in two ways:

- Clicking the "Run and Time" button in the MATLAB GUI while having some .m file open in the editor (added in R2012b).

- Programmatically, using:

```
profile on
<some code we want to test>
profile off
```

Below is some sample code and the result of its profiling:

```
function docTest
for ind1 = 1:100
    [~, var] = var(...
        sum(...
            sum(...
                randn(1000)));
end
spy
```
From the above we learn that the `spy` function takes about 25% of the total execution time. In the case of "real code", a function that takes such a large percentage of execution time would be a good candidate for optimization, as opposed to functions analogous to `var` and `cla` whose optimization should be avoided.

Moreover, it is possible to click on entries in the Function Name column to see a detailed breakdown of execution time for that entry. Here's the example of clicking `spy`:
It is also possible to profile memory consumption by executing `profile('-memory')` before running the Profiler.
Comparing execution time of multiple functions

The widely used combination of `tic` and `toc` can provide a rough idea of the execution time of a function or code snippets. For comparing several functions it shouldn't be used. Why? It is almost impossible to provide equal conditions for all code snippets to compare within a script using above solution. Maybe the functions share the same function space and common variables, so later called functions and code snippets already take advantage of previously initialized variables and functions. Also the there is no insight whether the JIT compiler would handle these subsequently called snippets equally.

The dedicated function for benchmarks is `timeit`. The following example illustrates its use.

There are the array `A` and the matrix `B`. It should be determined which row of `B` is the most similar.
to \( A \) by counting the number of different elements.

```matlab
function t = bench()
    A = [0 1 1 1 0 0];
    B = perms(A);

    % functions to compare
    fcns = {
        @() compare1(A,B);
        @() compare2(A,B);
        @() compare3(A,B);
        @() compare4(A,B);
    };

    % timeit
    t = cellfun(@timeit, fcns);
end

function Z = compare1(A,B)
    Z = sum(bsxfun(@eq, A,B), 2);
end

function Z = compare2(A,B)
    Z = sum(bsxfun(@xor, A, B), 2);
end

function Z = compare3(A,B)
    A = logical(A);
    Z = sum(B(:,~A), 2) + sum(~B(:,A), 2);
end

function Z = compare4(A,B)
    Z = pdist2( A, B, 'hamming', 'Smallest', 1 );
end
```

This way of benchmark was first seen in this answer.

It’s ok to be `single`!

---

**Overview:**

The default data type for numeric arrays in MATLAB is double. double is a floating point representation of numbers, and this format takes 8 bytes (or 64 bits) per value. In some cases, where e.g. dealing only with integers or when numerical instability is not an imminent issue, such high bit depth may not be required. For this reason, it is advised to consider the benefits of single precision (or other appropriate types):

- Faster execution time (especially noticeable on GPUs).
- Half the memory consumption: may succeed where double fails due to an out-of-memory error; more compact when storing as files.

Converting a variable from any supported data type to single is done using:

```matlab
sing_var = single(var);
```

Some commonly used functions (such as: zeros, eye, ones, etc.) that output double values by

https://riptutorial.com/
default, allow specifying the type/class of the output.

---

**Converting variables in a script to a non-default precision/type/class:**

As of July 2016, there exists no documented way to change the *default* MATLAB data type from double.

In MATLAB, new variables usually mimic the data types of variables used when creating them. To illustrate this, consider the following example:

```matlab
A = magic(3);
B = diag(A);
C = 20*B;
>> whos C
Name      Size            Bytes  Class     Attributes
C         3x1                24  double

A = single(magic(3)); % A is converted to "single"
B = diag(A);
C = B*double(20);     % The stricter type, which in this case is "single", prevails
D = single(size(C));  % It is generally advised to cast to the desired type explicitly.
>> whos C
Name      Size            Bytes  Class     Attributes
C         3x1                12  single
```

Thus, it may seem sufficient to cast/convert several initial variables to have the change permeate throughout the code - however this is **discouraged** (see Caveats & Pitfalls below).

---

**Caveats & Pitfalls:**

1. Repeated conversions are **discouraged** due to the introduction of numeric noise (when casting from single to double) or loss of information (when casting from double to single, or between certain integer types), e.g. :

   ```matlab
double(single(1.2)) == double(1.2)
an = 0
```

   This can be mitigated somewhat using *typecast*. See also Be aware of floating point inaccuracy.

2. Relying solely on implicit data-typing (i.e. what MATLAB guesses the type of the output of a computation should be) is **discouraged** due to several undesired effects that might arise:

   - **Loss of information**: when a **double** result is expected, but a careless combination of **single** and **double** operands yields **single** precision.
- **Unexpectedly high memory consumption**: when a single result is expected but a careless computation results in a double output.

- **Unnecessary overhead when working with GPUs**: when mixing `gpuArray` types (i.e. variables stored in VRAM) with non-`gpuArray` variables (i.e. those *usually* stored in RAM) the data will have to be transferred one way or the other before the computation can be performed. This operation takes time, and can be very noticeable in repetitive computations.

- **Errors when mixing floating-point types with integer types**: functions like `mtimes (·)` are not defined for mixed inputs of integer and floating point types - and will error. Functions like `times (.·)` are not defined at all for integer-type inputs - and will again error.

```matlab
>> ones(3,3,'int32')*ones(3,3,'int32')
Error using *  
MTIMES is not fully supported for integer classes. At least one input must be scalar.

>> ones(3,3,'int32').*ones(3,3,'double')
Error using .*
Integers can only be combined with integers of the same class, or scalar doubles.
```

For better code readability and reduced risk of unwanted types, a defensive approach is advised, where variables are explicitly cast to the desired type.

**See Also:**

- MATLAB Documentation: [Floating-Point Numbers](https://www.mathworks.com/help/index.html#b4xlfyj).

**rearrange a ND-array may improve the overall performance**

In some cases we need to apply functions to a set of ND-arrays. Let's look at this simple example.

```
A(:,:,1) = [1 2; 4 5];
A(:,:,2) = [11 22; 44 55];
B(:,:,1) = [7 8; 1 2];
B(:,:,2) = [77 88; 11 22];

A =
ans(:,:,1) =
   1    2
   4    5

ans(:,:,2) =
   11   22
   44   55
```
Both matrices are 3D, let's say we have to calculate the following:

```matlab
result = zeros(2,2);
...
for k = 1:2
    result(i,j) = result(i,j) + abs(A(i,j,k) - B(i,j,k));
...
```

If \( k \) is very large, this for-loop can be a bottleneck since MATLAB order the data in a column major fashion. So a better way to compute "result" could be:

```matlab
%A trying to exploit the column major ordering
Aprime = reshape(permute(A,[3,1,2]), [2,4]);
Bprime = reshape(permute(B,[3,1,2]), [2,4]);
```

Now we replace the above loop for as following:

```matlab
result = zeros(2,2);
... temp = abs(Aprime - Bprime);
for k = 1:2
    result(i,j) = result(i,j) + temp(k, i+2*(j-1));
...
```

We rearranged the data so we can exploit the cache memory. Permutation and reshape can be costly but when working with big ND-arrays the computational cost related to these operations is much lower than working with not arranged arrays.

**The importance of preallocation**
Arrays in MATLAB are held as continuous blocks in memory, allocated and released automatically by MATLAB. MATLAB hides memory management operations such as resizing of an array behind easy to use syntax:

\begin{verbatim}
   a = 1:4
   a =
    1  2  3  4
   a(5) = 10   % or alternatively a = [a, 10]
   a =
    1  2  3  4  10
\end{verbatim}

It is important to understand that the above is not a trivial operation, \(a(5) = 10\) will cause MATLAB to allocate a new block of memory of size 5, copy the first 4 numbers over, and set the 5'th to 10. That's a \(O(\text{numel}(a))\) operation, and not \(O(1)\).

Consider the following:

\begin{verbatim}
clear all
n=12345678;
a=0;
tic
for i = 2:n
    a(i) = sqrt(a(i-1)) + i;
end
toc
Elapsed time is 3.004213 seconds.
\end{verbatim}

\(a\) is reallocated \(n\) times in this loop (excluding some optimizations undertaken by MATLAB)! Note that MATLAB gives us a warning:

"The variable 'a' appears to change size on every loop iteration. Consider preallocating for speed."

What happens when we preallocate?

\begin{verbatim}
a=zeros(1,n);
tic
for i = 2:n
    a(i) = sqrt(a(i-1)) + i;
end
toc
Elapsed time is 0.410531 seconds.
\end{verbatim}

We can see the runtime is reduced by an order of magnitude.

Methods for preallocation:
MATLAB provides various functions for allocation of vectors and matrices, depending on the specific requirements of the user. These include: `zeros`, `ones`, `nan`, `eye`, `true` etc.

```matlab
a = zeros(3)       % Allocates a 3-by-3 matrix initialized to 0
a =
    0     0     0
    0     0     0
    0     0     0

a = zeros(3, 2)     % Allocates a 3-by-2 matrix initialized to 0
a =
    0     0
    0     0
    0     0

a = ones(2, 3, 2)      % Allocates a 3 dimensional array (2-by-3-by-2) initialized to 1
a(:,:,1) =
    1     1     1
    1     1     1

a(:,:,2) =
    1     1     1
    1     1     1

a = ones(1, 3) * 7  % Allocates a row vector of length 3 initialized to 7
a =
    7     7     7
```

A data type can also be specified:

```matlab
a = zeros(2, 1, 'uint8');  % allocates an array of type uint8
```

It is also easy to clone the size of an existing array:

```matlab
a = ones(3, 4);       % a is a 3-by-4 matrix of 1's
b = zeros(size(a));  % b is a 3-by-4 matrix of 0's

And clone the type:

```matlab
a = ones(3, 4, 'single');       % a is a 3-by-4 matrix of type single
b = zeros(2, 'like', a);       % b is a 2-by-2 matrix of type single
```

note that 'like' also clones `complexity` and `sparsity`.

Preallocation is implicitly achieved using any function that returns an array of the final required size, such as `rand`, `gallery`, `kron`, `bsxfun`, `colon` and many others. For example, a common way to allocate vectors with linearly varying elements is by using the colon operator (with either the 2- or 3-operand variant):

```matlab
https://riptutorial.com/ 172
```
```matlab
a = 1:3
a =
    1     2     3

a = 2:-3:-4
a =
     2    -1    -4
```

Cell arrays can be allocated using the `cell()` function in much the same way as `zeros()`.

```matlab
a = cell(2,3)
a =
    []    []    []
    []    []    []
```

Note that cell arrays work by holding pointers to the locations in memory of cell contents. So all preallocation tips apply to the individual cell array elements as well.

Chapter 26: Programming Utilities

Examples

Simple timer in MATLAB

The following is a timer that fires at a fixed interval. It's timeout is defined by \texttt{Period} and it invokes a callback defined by \texttt{TimerFcn} upon timeout.

```matlab
  t = timer;
  t.TasksToExecute = Inf;
  t.Period = 0.01; % timeout value in seconds
  t.TimerFcn = @(myTimerObj, thisEvent)disp('hello'); % timer callback function
  t.ExecutionMode = 'fixedRate';
  start(t)
  pause(inf);
```

Read Programming Utilities online: https://riptutorial.com/matlab/topic/1655/programming-utilities
Chapter 27: Reading large files

Examples

textscan

Assume you have formatted data in a large text file or string, e.g.

```
Data,2015-09-16,15:41:52;781,780.000000,0.0034,2.2345
Data,2015-09-16,15:41:52;791,790.000000,0.1255,96.5948
Data,2015-09-16,15:41:52;801,800.000000,1.5123,0.0043
```

one may use `textscan` to read this quite fast. To do so, get a file identifier of the text file with `fopen`:

```
fid = fopen('path/to/myfile');
```

Assume for the data in this example, we want to ignore the first column "Data", read the date and time as strings, and read the rest of the columns as doubles, i.e.

<table>
<thead>
<tr>
<th>Data</th>
<th>2015-09-16</th>
<th>15:41:52</th>
<th>801</th>
<th>800.000000</th>
<th>1.5123</th>
<th>0.0043</th>
</tr>
</thead>
<tbody>
<tr>
<td>ignore</td>
<td>string</td>
<td>string</td>
<td>double</td>
<td>double</td>
<td>double</td>
<td></td>
</tr>
</tbody>
</table>

To do this, call:

```
data = textscan(fid,'%*s %s %s %f %f %f','Delimiter',',');
```

The asterisk in `%*s` means "ignore this column". `%s` means "interpret as a string". `%f` means "interpret as doubles (floats)". Finally, `'Delimiter',','` states that all commas should be interpreted as the delimiter between each column.

To sum up:

```
fid = fopen('path/to/myfile');
data = textscan(fid,'%*s %s %s %f %f %f','Delimiter',',');
```

data now contains a cell array with each column in a cell.

Date and time strings to numeric array fast

Converting date and time strings to numeric arrays can be done with `datenum`, though it may take as much as half the time of reading a large data file.

Consider the data in example Textscan. By, again, using textscan and interpret date and time as integers, they can rapidly be converted into a numeric array.

I.e. a line in the example data would be interpreted as:

```
https://riptutorial.com/ 175
```
which will be read as:

```matlab
fid = fopen('path/to/myfile');
data = textscan(fid, '%*s %f %f %f %f %f %f %f %f %f %f', 'Delimiter', ',+-;');
fclose(fid);

Now:

y = data{1}; % year
m = data{2}; % month
d = data{3}; % day
H = data{4}; % hours
M = data{5}; % minutes
S = data{6}; % seconds
F = data{7}; % milliseconds

% Translation from month to days
ms = [0, 31, 59, 90, 120, 151, 181, 212, 243, 273, 304, 334];

n = length(y); % Number of elements
Time = zeros(n, 1); % Declare numeric time array

% Algorithm for calculating numeric time array
for k = 1:n
    Time(k) = y(k)*365 + ms(m(k)) + d(k) + floor(y(k)/4)...
        - floor(y(k)/100) + floor(y(k)/400) + (mod(y(k), 4)~=0)...
        - (mod(y(k), 100)~=0) + (mod(y(k), 400)~=0)...
        + (H(k)*3600 + M(k)*60 + S(k) + F(k)/1000)/86400 + 1;
end
```

Using `datenum` on 566,678 elements required 6.626570 seconds, whilst the method above required 0.048334 seconds, i.e. 0.73% of the time for `datenum` or ~137 times faster.

Read Reading large files online: https://riptutorial.com/matlab/topic/9023/reading-large-files
Chapter 28: Set operations

Syntax

1. C = union(A,B);
2. C = intersect(A,B);
3. C = setdiff(A,B);
4. a = ismember(A,x);

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>A,B</td>
<td>sets, possibly matrices or vectors</td>
</tr>
<tr>
<td>x</td>
<td>possible element of a set</td>
</tr>
</tbody>
</table>

Examples

Elementary set operations

It's possible to perform elementary set operations with Matlab. Let's assume we have given two vectors or arrays

```matlab
A = randi([0 10],1,5);
B = randi([-1 9],1,5);
```

and we want to find all elements which are in A and in B. For this we can use

```matlab
C = intersect(A,B);
```

C will include all numbers which are part of A and part of B. If we also want to find the position of these elements we call

```matlab
[C,pos] = intersect(A,B);
```

pos is the position of these elements such that C == A(pos).

Another basic operation is the union of two sets

```matlab
D = union(A,B);
```

Herby contains D all elements of A and B.
Note that $A$ and $B$ are hereby treated as sets which means that it does not matter how often an element is part of $A$ or $B$. To clarify this one can check $D \equiv \text{union}(D,C)$.

If we want to obtain the data that is in 'A' but not in 'B' we can use the following function

$$E = \text{setdiff}(A,B);$$

We want to note again that this are sets such that following statement holds $D \equiv \text{union}(E,B)$.

Suppose we want to check if

$$x = \text{randi}([-10 10],1,1);$$

is an element of either $A$ or $B$ we can execute the command

$$\begin{align*}
a &= \text{ismember}(A,x); \\
b &= \text{ismember}(B,x);
\end{align*}$$

If $a==1$ then $x$ is element of $A$ and $x$ is no element is $a==0$. The same goes for $B$. If $a==1 \&\& b==1$ $x$ is also an element of $C$. If $a == 1 || b == 1$ $x$ is element of $D$ and if $a == 1 || b == 0$ it's also element of $E$.

Read Set operations online: https://riptutorial.com/matlab/topic/3242/set-operations
Chapter 29: Undocumented Features

Remarks

- Using undocumented features is considered a risky practice\(^1\), as these features may change without notice or simply work differently on different MATLAB versions. For this reason, it is advised to employ defensive programming techniques such as enclosing undocumented pieces of code within `try/catch` blocks with documented fallbacks.

Examples

C++ compatible helper functions

The use of Matlab Coder sometimes denies the use of some very common functions, if they are not compatible to C++. Relatively often there exist undocumented helper functions, which can be used as replacements.

Here is a comprehensive list of supported functions.

And following a collection of alternatives, for non-supported functions:

The functions `sprintf` and `sprintfc` are quite similar, the former returns a character array, the latter a cell string:

```matlab
str = sprintf('%i',x)   % returns '5' for x = 5
str = sprintfc('%i',x)  % returns {'5'} for x = 5
```

However, `sprintfc` is compatible with C++ supported by Matlab Coder, and `sprintf` is not.

Color-coded 2D line plots with color data in third dimension

In MATLAB versions prior to R2014b, using the old HG1 graphics engine, it was not obvious how to create color coded 2D line plots. With the release of the new HG2 graphics engine arose a new undocumented feature introduced by Yair Altman:

```matlab
n = 100;  
x = linspace(-10,10,n); y = x.^2;  
p = plot(x,y,'r', 'LineWidth',5);  

% modified jet-colormap  
cd = [uint8(jet(n)*255) uint8(ones(n,1))].';  

drawnow  
set(p.Edge, 'ColorBinding','interpolated', 'ColorData',cd)
```
Semi-transparent markers in line and scatter plots

Since Matlab R2014b it is easily possible to achieve semi-transparent markers for line and scatter plots using undocumented features introduced by Yair Altman.

The basic idea is to get the hidden handle of the markers and apply a value < 1 for the last value in the `EdgeColorData` to achieve the desired transparency.

Here we go for `scatter`:

```matlab
%// example data
x = linspace(0,3*pi,200);
y = cos(x) + rand(1,200);

%// plot scatter, get handle
h = scatter(x,y);
drawnow; %// important

%// get marker handle
hMarkers = h.MarkerHandle;

%// get current edge and face color
edgeColor = hMarkers.EdgeColorData
faceColor = hMarkers.FaceColorData

%// set face color to the same as edge color
faceColor = edgeColor;

%// opacity
opa = 0.3;

%// set marker edge and face color
hMarkers.EdgeColorData = uint8( [edgeColor(1:3); 255*opa] );
```
```matlab
hMarkers.FaceColorData = uint8( [faceColor(1:3); 255*opa] );
```

and for a line plot

```matlab
%% example data
x = linspace(0,3*pi,200);
y1 = cos(x);
y2 = sin(x);

%% plot scatter, get handle
h1 = plot(x,y1,'o-','MarkerSize',15); hold on
h2 = plot(x,y2,'o-','MarkerSize',15);
drawnow; %// important

%% get marker handle
h1Markers = h1.MarkerHandle;
h2Markers = h2.MarkerHandle;

%% get current edge and face color
edgeColor1 = h1Markers.EdgeColorData;
edgeColor2 = h2Markers.EdgeColorData;

%% set face color to the same as edge color
faceColor1 = edgeColor1;
faceColor2 = edgeColor2;

%% opacity
opa = 0.3;

%% set marker edge and face color
h1Markers.EdgeColorData = uint8( [edgeColor1(1:3); 255*opa] );
```
Markers.FaceColorData = uint8([faceColor1(1:3); 255*opa]);
Markers.EdgeColorData = uint8([edgeColor2(1:3); 255*opa]);
Markers.FaceColorData = uint8([faceColor2(1:3); 255*opa]);

The marker handles, which are used for the manipulation, are created with the figure. The `drawnow` command is ensuring the creation of the figure before subsequent commands are called and avoids errors in case of delays.

**Contour Plots - Customise the Text Labels**

When displaying labels on contours Matlab doesn't allow you to control the format of the numbers, for example to change to scientific notation.

The individual text objects are normal text objects but how you get them is undocumented. You access them from the `TextPrims` property of the contour handle.

```matlab
figure
[X,Y]=meshgrid(0:100,0:100);
Z=(X+Y.^2)*1e10;
[C,h]=contour(X,Y,Z);
h.ShowText='on';
drawnow();
txt = get(h,'TextPrims');
v = str2double(get(txt,'String'));
for ii=1:length(v)
    set(txt(ii),'String',sprintf('%0.3e',v(ii)))
end
```

*Note: that you must add a `drawnow` command to force Matlab to draw the contours, the number and location of the txt objects are only determined when the contours are actually drawn so the text...*
objects are only created then.

The fact the txt objects are created when the contours are drawn means that they are recalculated every time the plot is redrawn (for example figure resize). To manage this you need to listen to the undocumented event MarkedClean:

```matlab
function customiseContour
    figure
    [X,Y]=meshgrid(0:100,0:100);
    Z=(X+Y.^2)*1e10;
    [C,h]=contour(X,Y,Z);
    h.ShowText='on';
    % add a listener and call your new format function
    addlistener(h,'MarkedClean',@(a,b)ReFormatText(a))
end

function ReFormatText(h)
    % get all the text items from the contour
    t = get(h,'TextPrims');
    for ii=1:length(t)
        % get the current value (Matlab changes this back when it
        % redraws the plot)
        v = str2double(get(t(ii),'String'));
        % Update with the format you want - scientific for example
        set(t(ii),'String',sprintf('%0.3e',v));
    end
end
```

Example tested using Matlab r2015b on Windows

Appending / adding entries to an existing legend
Existing legends can be difficult to manage. For example, if your plot has two lines, but only one of them has a legend entry and that should stay this way, then adding a third line with a legend entry can be difficult. Example:

```matlab
figure
hold on
fplot(@sin)
fplot(@cos)
legend sin  % Add only a legend entry for sin
hTan = fplot(@tan);  % Make sure to get the handle, hTan, to the graphics object you want to add to the legend
```

Now, to add a legend entry for $\tan$, but not for $\cos$, any of the following lines won't do the trick; they all fail in some way:

```matlab
legend tangent  % Replaces current legend -> fail
legend -DynamicLegend  % Undocumented feature, adds 'cos', which shouldn't be added -> fail
legend sine tangent  % Sets cos DisplayName to 'tangent' -> fail
legend sine '' tangent  % Sets cos DisplayName, albeit empty -> fail
legend(f)
```

Luckily, an undocumented legend property called `PlotChildren` keeps track of the children of the parent figure\(^1\). So, the way to go is to explicitly set the legend's children through its `PlotChildren` property as follows:

```matlab
hTan.DisplayName = 'tangent';  % Set the graphics object's display name
l = legend;  
1 = l.PlotChildren(end + 1) = hTan;  % Append the graphics handle to legend's plot children
```

The legend updates automatically if an object is added or removed from its `PlotChildren` property.

\(^1\) Indeed: figure. You can add any figure's child with the `DisplayName` property to any legend in the figure, e.g. from a different subplot. This is because a legend in itself is basically an axes object.

Tested on MATLAB R2016b

**Scatter plot jitter**

The `scatter` function has two undocumented properties `'jitter'` and `'jitterAmount'` that allow to jitter the data on the x-axis only. This dates back to Matlab 7.1 (2005), and possibly earlier.

To enable this feature set the `'jitter'` property to `'on'` and set the `'jitterAmount'` property to the desired absolute value (the default is 0.2).

This is very useful when we want to visualize overlapping data, for example:

```matlab
scatter(ones(1,10), ones(1,10), 'jitter', 'on', 'jitterAmount', 0.5);
```

Chapter 30: Usage of `accumarray()` Function

Introduction

accumarray allows to aggregate items of an array in various ways, potentially applying some function to the items in the process. accumarray can be thought of as a lightweight reducer (see also: Introduction to MapReduce).

This topic will contain common scenarios where accumarray is especially useful.

Syntax

- `accumarray(subscriptArray, valuesArray)`
- `accumarray(subscriptArray, valuesArray, sizeOfOutput)`
- `accumarray(subscriptArray, valuesArray, sizeOfOutput, funcHandle)`
- `accumarray(subscriptArray, valuesArray, sizeOfOutput, funcHandle, fillVal)`
- `accumarray(subscriptArray, valuesArray, sizeOfOutput, funcHandle, fillVal, isSparse)`

Parameters

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>subscriptArray</td>
<td>Subscript matrix, specified as a vector of indices, matrix of indices, or cell array of index vectors.</td>
</tr>
<tr>
<td>valuesArray</td>
<td>Data, specified as a vector or a scalar.</td>
</tr>
<tr>
<td>sizeOfOutput</td>
<td>Size of output array, specified as a vector of positive integers.</td>
</tr>
<tr>
<td>funcHandle</td>
<td>Function to be applied to each set of items during aggregation, specified as a function handle or[].</td>
</tr>
<tr>
<td>fillVal</td>
<td>Fill value, for when subs does not reference each element in the output.</td>
</tr>
<tr>
<td>isSparse</td>
<td>Should the output be a sparse array?</td>
</tr>
</tbody>
</table>

Remarks

- Introduced in MATLAB v7.0.

References:

2. accumarray in the official MATLAB documentation.
Examples

Finding the maximum value among elements grouped by another vector

This is an official MATLAB example

Consider the following code:

\[
\begin{align*}
\text{month} &= [1;1;2;3;8;1;3;4;9;11;9;12;3;4;11]; \\
\text{temperature} &= [57;61;60;62;45;59;64;66;40;56;38;65;61;64;55]; \\
\text{maxTemp} &= \text{accumarray(month,temperature,[],@max)};
\end{align*}
\]

The image below demonstrates the computation process done by \texttt{accumarray} in this case:

<table>
<thead>
<tr>
<th>month</th>
<th>temperature</th>
<th>maxTemp</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>57</td>
<td>max([57, 61, 59])</td>
</tr>
<tr>
<td>1</td>
<td>61</td>
<td>max([60])</td>
</tr>
<tr>
<td>2</td>
<td>60</td>
<td>max([62, 64, 61])</td>
</tr>
<tr>
<td>3</td>
<td>62</td>
<td>max([66, 64])</td>
</tr>
<tr>
<td>8</td>
<td>45</td>
<td>max([64])</td>
</tr>
<tr>
<td>1</td>
<td>59</td>
<td>max([45])</td>
</tr>
<tr>
<td>3</td>
<td>64</td>
<td>max([40, 38])</td>
</tr>
<tr>
<td>4</td>
<td>66</td>
<td>max([56, 55])</td>
</tr>
<tr>
<td>9</td>
<td>40</td>
<td>max([55])</td>
</tr>
<tr>
<td>11</td>
<td>56</td>
<td>max([65])</td>
</tr>
<tr>
<td>9</td>
<td>38</td>
<td>max([65])</td>
</tr>
<tr>
<td>12</td>
<td>65</td>
<td>max([65])</td>
</tr>
<tr>
<td>3</td>
<td>61</td>
<td>max([65])</td>
</tr>
<tr>
<td>4</td>
<td>64</td>
<td>max([65])</td>
</tr>
<tr>
<td>11</td>
<td>55</td>
<td>max([65])</td>
</tr>
</tbody>
</table>

\[\text{maxTemp} = \text{accumarray(subs,val,[],@max)}\]

In this example, all values that have the same month are first collected, and then the function specified by the 4th input to \texttt{accumarray} (in this case, \texttt{@max}) is applied to each such set.

Apply Filter to Image Patches and Set Each Pixel as the Mean of the Result of Each Patch

Many modern Image Processing algorithms use patches are their basic element to work on. For instance one could denoise patches (See BM3D Algorithm).

Yet when building the image form the processed patches we have many results for the same pixel.
One way to deal with it is taking the average (Empirical Mean) of all values of the same pixel.

The following code shows how to break an image into patches and then reconstruct the image from patches using the average by using \( \texttt{accumarray()} \):

```matlab
numRows = 5;
numCols = 5;
numRowsPatch = 3;
numColsPatch = 3;

% The Image
mI = rand([numRows, numCols]);

% Decomposing into Patches - Each pixel is part of many patches (Neglecting % boundaries, each pixel is part of \((\text{numRowsPatch} \times \text{numColsPatch})\) patches).
mY = ImageToColumnsSliding(mI, [numRowsPatch, numColsPatch]);

% Here one would apply some operation which works on patches

% Creating image of the index of each pixel
mFIdx = reshape(1:(numRows * numCols), [numRows, numCols]);

% Creating patches of the same indices
mSubsAccu = ImageToColumnsSliding(mFIdx, [numRowsPatch, numColsPatch]);

% Reconstruct the image - Option A
mO = accumarray(mSubsAccu(:), mY(:)) ./ accumarray(mSubsAccu(:), 1);

% Reconstruct the image - Option B
mO = accumarray(mSubsAccu, mY(:), [(numRows * numCols), 1], @(x) mean(x));

% Reshape the Vector into the Image
mO = reshape(mO, [numRows, numCols]);
```

Chapter 31: Useful tricks

Examples

Useful functions that operate on cells and arrays

This simple example provides an explanation on some functions I found extremely useful since I have started using MATLAB: **cellfun**, **arrayfun**. The idea is to take an array or cell class variable, loop through all its elements and apply a dedicated function on each element. An applied function can either be anonymous, which is usually a case, or any regular function define in a *.m file.

Let's start with a simple problem and say we need to find a list of *.mat files given the folder. For this example, first let's create some *.mat files in a current folder:

```matlab
for n=1:10; save(sprintf('mymatfile%d.mat',n)); end
```

After executing the code, there should be 10 new files with extension *.mat. If we run a command to list all *.mat files, such as:

```matlab
mydir = dir('*.mat');
```

we should get an array of elements of a dir structure; MATLAB should give a similar output to this one:

```
10x1 struct array with fields:
   name
date
bytes
isdir
datenum
```

As you can see each element of this array is a structure with couple of fields. All information are indeed important regarding each file but in 99% I am rather interested in file names and nothing else. To extract information from a structure array, I used to create a local function that would involve creating temporal variables of a correct size, for loops, extracting a name from each element, and save it to created variable. Much easier way to achieve exactly the same result is to use one of the aforementioned functions:

```matlab
mydirlist = arrayfun(@(x) x.name, dir('*.mat'), 'UniformOutput', false)
mydirlist =
   'mymatfile1.mat'
   'mymatfile10.mat'
   'mymatfile2.mat'
   'mymatfile3.mat'
   'mymatfile4.mat'
   'mymatfile5.mat'
   'mymatfile6.mat'
   'mymatfile7.mat'
```
How this function works? It usually takes two parameters: a function handle as the first parameter and an array. A function will then operate on each element of a given array. The third and fourth parameters are optional but important. If we know that an output will not be regular, it must be saved in cell. This must be point out setting \texttt{false} to \texttt{UniformOutput}. By default this function attempts to return a regular output such as a vector of numbers. For instance, let’s extract information about how much of disc space is taken by each file in bytes:

```matlab
mydirbytes = arrayfun(@(x) x.bytes, dir('*.mat'))
mydirbytes =
34560
34560
34560
34560
34560
34560
34560
34560
34560
34560
```

or kilobytes:

```matlab
mydirbytes = arrayfun(@(x) x.bytes/1024, dir('*.mat'))
mydirbytes =
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
33.7500
```

This time the output is a regular vector of double. \texttt{UniformOutput} was set to \texttt{true} by default.

cellfun is a similar function. The difference between this function and \texttt{arrayfun} is that \texttt{cellfun} operates on cell class variables. If we wish to extract only names given a list of file names in a cell 'mydirlist', we would just need to run this function as follows:

```matlab
mydirnames = cellfun(@(x) x(1:end-4), mydirlist, 'UniformOutput', false)
mydirnames =
'mymatfile1'
'mymatfile10'
'mymatfile2'
'mymatfile3'
'mymatfile4'
'mymatfile5'
'mymatfile6'
'mymatfile7'
'mymatfile8'
```
Again, as an output is not a regular vector of numbers, an output must be saved in a cell variable.

In the example below, I combine two functions in one and return only a list of file names without an extension:

```matlab
cellfun(@(x) x(1:end-4), arrayfun(@(x) x.name, dir('*.mat'), 'UniformOutput', false), 'UniformOutput', false)
ans =
    'mymatfile1'
    'mymatfile10'
    'mymatfile2'
    'mymatfile3'
    'mymatfile4'
    'mymatfile5'
    'mymatfile6'
    'mymatfile7'
    'mymatfile8'
    'mymatfile9'
```

It is crazy but very possible because `arrayfun` returns a cell which is expected input of `cellfun`; a side note to this is that we can force any of those functions to return results in a cell variable by setting `UniformOutput` to false, explicitly. We can always get results in a cell. We may not be able to get results in a regular vector.

There is one more similar function that operates on fields a structure: `structfun`. I have not particularly found it as useful as the other two but it would shine in some situations. If for instance one would like to know which fields are numeric or non-numeric, the following code can give the answer:

```matlab
structfun(@(x) ischar(x), mydir(1))
```

The first and the second field of a `dir` structure is of a char type. Therefore, the output is:

```
1
1
0
0
0
```

Also, the output is a logical vector of `true / false`. Consequently, it is regular and can be saved in a vector; no need to use a cell class.

**Code Folding Preferences**

It is possible to change Code Folding preference to suit your need. Thus code folding can be set enable/unable for specific constructs (ex: if block, for loop, Sections ...).

To change folding preferences, go to Preferences -> Code Folding:
Then you can choose which part of the code can be folded.

Some information:

- Note that you can also expand or collapse all of the code in a file by placing your cursor anywhere within the file, right-click, and then select Code Folding > Expand All or Code Folding > Fold All from the context menu.
- Note that folding is persistent, in the sense that part of the code that has been expanded/collapsed will keep their status after Matlab or the m-file has been closed and is re-open.

**Example: To enable folding for sections:**

An interesting option is to enable to fold Sections. Sections are delimited by two percent signs (%%).
Example: To enable it check the "Sections" box:

Then instead of seeing a long source code similar to:

```bash
%% LOAD

% code to load data
% ...
% ...
% ...
% ...
% ...
% ...
% ...
% ...

%% TREAT

% code to run the model
% ...
% ...
% ...
% ...
% ...
% ...
% ...
% ...

%% OUTPUT

% code to output results
% ...
% ...
% ...
% ...
% ...
% ...
% ...
% ...
```

You will be able to fold sections to have a general overview of your code:
Extract figure data

On a few occasions, I have had an interesting figure I saved but I lost an access to its data. This example shows a trick how to achieve extract information from a figure.

The key functions are `findobj` and `get`. `findobj` returns a handler to an object given attributes or properties of the object, such as `Type`, `Color`, etc. Once a line object has been found, `get` can return any value held by properties. It turns out that the `Line` objects hold all data in following properties: `XData`, `YData`, and `ZData`; the last one is usually 0 unless a figure contains a 3D plot.

The following code creates an example figure that shows two lines a sin function and a threshold and a legend

```matlab
% code to output results
\% ...
\% ...
\% ...
\% ...
\% ...
\% ...
\% ...
```

```matlab
t = (0:1/10:1-1/10)';
y = sin(2*pi*t);
plot(t,y);
hold on;
plot([0 0.9],[0 0], 'k-');
hold off;
legend({'sin' 'threshold'});
```

The first use of `findobj` returns two handlers to both lines:

```matlab
findobj(gcf, 'Type', 'Line')
ans =
          2x1 Line array:
            Line    (threshold)
            Line    (sin)
```

To narrow the result, `findobj` can also use combination of logical operators `-and`, `-or` and property names. For instance, I can find a line object whose `DisplayName` is `sin` and read its `XData` and `YData`.

```matlab
lineh = findobj(gcf, 'Type', 'Line', '-and', 'DisplayName', 'sin');
xdata = get(lineh, 'XData');
ydata = get(lineh, 'YData');
```
and check if the data are equal.

```matlab
isequal(t(:),xdata(:))
ans =
  1
isequal(y(:),ydata(:))
ans =
  1
```

Similarly, I can narrow my results by excluding the black line (threshold):

```matlab
lineh = findobj(gcf, 'Type', 'Line', '-not', 'Color', 'k');
xdata = get(lineh, 'XData');
ydata = get(lineh, 'YData');
```

and last check confirms that data extracted from this figure are the same:

```matlab
isequal(t(:),xdata(:))
ans =
  1
isequal(y(:),ydata(:))
ans =
  1
```

**Functional Programming using Anonymous Functions**

Anonymous functions can be used for functional programming. The main problem to solve is that there is no native way for anchoring a recursion, but this can still be implemented in a single line:

```matlab
if_ = @(bool, tf) tf{2-bool}();
```

This function accepts a boolean value and a cell array of two functions. The first of those functions is evaluated if the boolean value evaluates as true, and the second one if the boolean value evaluates as false. We can easily write the factorial function now:

```matlab
fac = @(n,f) if_(n>1, {@()n*f(n-1,f), @()1});
```

The problem here is that we cannot directly invoke a recursive call, as the function is not yet assigned to a variable when the right hand side is evaluated. We can however complete this step by writing

```matlab
factorial_ = @(n)fac(n,fac);
```

Now `@(n)fac(n,fac)` evaulates the factorial function recursively. Another way to do this in functional programming using a y-combinator, which also can easily be implemented:

```matlab
y_ = @(f) @(n)f(n,f);
```

With this tool, the factorial function is even shorter:
factorial_ = y_(fac);

Or directly:

factorial_ = y_(@(n,f) if_(n>1, {@()n*f(n-1,f), @()1)});

Save multiple figures to the same .fig file

By putting multiple figure handles into a graphics array, multiple figures can be saved to the same .fig file

```matlab
h(1) = figure;
scatter(rand(1,100),rand(1,100));

h(2) = figure;
scatter(rand(1,100),rand(1,100));

h(3) = figure;
scatter(rand(1,100),rand(1,100));

savefig(h,'ThreeRandomScatterplots.fig');
close(h);
```

This creates 3 scatterplots of random data, each part of graphic array h. Then the graphics array can be saved using savefig like with a normal figure, but with the handle to the graphics array as an additional argument.

An interesting side note is that the figures will tend to stay arranged in the same way that they were saved when you open them.

Comment blocks

If you want to comment part of your code, then comment blocks may be useful. Comment block starts with a %{ in a new line and ends with %} in another new line:

```matlab
a = 10;
b = 3;
%
c = a*b;
d = a-b;
%
```

This allows you fo fold the sections that you commented to make the code more clean and compact.

These blocks are also useful for toggling on/off parts of your code. All you have to do to uncomment the block is add another % before it strats:

```matlab
a = 10;
b = 3;
%%{ <-- another % over here
```
Sometimes you want to comment out a section of the code, but without affecting its indentation:

```matlab
for k = 1:a
    b = b*k;
    c = c-b;
    d = d*c;
    disp(b)
end
```

Usually, when you mark a block of code and press Ctrl+r for commenting it out (by that adding the % automatically to all lines, then when you press later Ctrl+i for auto indentation, the block of code moves from its correct hierarchical place, and moved too much to the right:

```matlab
for k = 1:a
    b = b*k;
    % c = c-b;
    % d = d*c;
    disp(b)
end
```

A way to solve this is to use comment blocks, so the inner part of the block stays correctly indented:

```matlab
for k = 1:a
    b = b*k;
    %{ c = c-b;
        d = d*c;
    %}
    disp(b)
end
```

Read Useful tricks online: https://riptutorial.com/matlab/topic/4179/useful-tricks
Chapter 32: Using functions with logical output

Examples

All and Any with empty arrays

Special care needs to be taken when there is a possibility that an array become an empty array when it comes to logical operators. It is often expected that if \( \text{all}(A) \) is true then \( \text{any}(A) \) must be true and if \( \text{any}(A) \) is false, \( \text{all}(A) \) must also be false. That is not the case in MATLAB with empty arrays.

```matlab
>> any([])
an =
0
>> all([])
an =
1
```

So if for example you are comparing all elements of an array with a certain threshold, you need to be aware of the case where the array is empty:

```matlab
>> A=1:10;
>> all(A>5)
an =
0
>> A=1:0;
>> all(A>5)
an =
1
```

Use the built-in function `isempty` to check for empty arrays:

```matlab
a = [];
isempty(a)
an =
1
```

Read Using functions with logical output online: https://riptutorial.com/matlab/topic/5608/using-functions-with-logical-output
Chapter 33: Using serial ports

Introduction

Serial ports are a common interface for communicating with external sensors or embedded systems such as Arduinos. Modern serial communications are often implemented over USB connections using USB-serial adapters. MATLAB provides built-in functions for serial communications, including RS-232 and RS-485 protocols. These functions can be used for hardware serial ports or "virtual" USB-serial connections. The examples here illustrate serial communications in MATLAB.

Parameters

<table>
<thead>
<tr>
<th>Serial port parameter</th>
<th>what it does</th>
</tr>
</thead>
<tbody>
<tr>
<td>\textbf{BaudRate}</td>
<td>Sets the baudrate. The most common today is 57600, but 4800, 9600, and 115200 are frequently seen as well</td>
</tr>
<tr>
<td>\textbf{InputBufferSize}</td>
<td>The number of bytes kept in memory. Matlab has a FIFO, which means that new bytes will be discarded. The default is 512 bytes, but it can easily be set to 20MB without issue. There are only a few edge cases where the user would want this to be small</td>
</tr>
<tr>
<td>\textbf{BytesAvailable}</td>
<td>The number of bytes waiting to be read</td>
</tr>
<tr>
<td>\textbf{ValuesSent}</td>
<td>The number of bytes sent since the port was opened</td>
</tr>
<tr>
<td>\textbf{ValuesReceived}</td>
<td>The number of bytes read since the port was opened</td>
</tr>
<tr>
<td>\textbf{BytesAvailableFcn}</td>
<td>Specify the callback function to execute when a specified number of bytes is available in the input buffer, or a terminator is read</td>
</tr>
<tr>
<td>\textbf{BytesAvailableFcnCount}</td>
<td>Specify the number of bytes that must be available in the input buffer to generate a bytes-available event</td>
</tr>
<tr>
<td>\textbf{BytesAvailableFcnMode}</td>
<td>Specify if the bytes-available event is generated after a specified number of bytes is available in the input buffer, or after a terminator is read</td>
</tr>
</tbody>
</table>

Examples

Creating a serial port on Mac/Linux/Windows
% Define serial port with a baud rate of 115200
rate = 115200;
if ispc
    s = serial('COM1', 'BaudRate',rate);
elseismac
    % Note that on OSX the serial device is uniquely enumerated. You will
    % have to look at /dev/tty.* to discover the exact signature of your
    % serial device
    s = serial('/dev/tty.usbserial-A104VFT7', 'BaudRate',rate);
elseif isunix
    s = serial('/dev/ttyusb0', 'BaudRate',rate);
end

% Set the input buffer size to 1,000,000 bytes (default: 512 bytes).
s.InputBufferSize = 1000000;

% Open serial port
fopen(s);

Reading from the serial port

Assuming you created the serial port object s as in this example, then

% Read one byte
data = fread(s, 1);

% Read all the bytes, version 1
data = fread(s);

% Read all the bytes, version 2
data = fread(s, s.BytesAvailable);

% Close the serial port
fclose(s);

Closing a serial port even if lost, deleted or overwritten

Assuming you created the serial port object s as in this example, then to close it

fclose(s)

However, sometimes you can accidentally lose the port (e.g. clear, overwrite, change scope, etc...), and fclose(s) will no longer work. The solution is easy

fclose(instrfindall)

More info at instrfindall().

Writing to the serial port

Assuming you created the serial port object s as in this example, then

% Write one byte
fwrite(s, 255);

% Write one 16-bit signed integer
fwrite(s, 32767, 'int16');

% Write an array of unsigned 8-bit integers
fwrite(s,[48 49 50],'uchar');

% Close the serial port
fclose(s);

Chosing your communication mode

Matlab supports synchronous and asynchronous communication with a serial port. It is important to chose the right communication mode. The choice will depend on:

- how the instrument you are communicating with behave.
- what other functions your main program (or GUI) will have to do aside from managing the serial port.

I'll define 3 different cases to illustrate, from the simplest to the most demanding. For the 3 examples, the instrument I am connecting to is a circuit board with an inclinometer, which can work in the 3 modes I will be describing below.

Mode 1: Synchronous (Master/Slave)

This mode is the simplest one. It correspond to the case where the PC is the Master and the instrument is the slave. The instrument does not send anything to the serial port on it's own, it only replies an answer after being asked a question/command by the Master (the PC, your program). For example:

- The PC sends a command: "Give me a measurement now"
- The instrument receive the command, take the measurement then send back the measurement value to the serial line: "The inclinometer value is XXX".

OR

- The PC sends a command: "Change from mode X to mode Y"
- The instrument receive the command, execute it, then send a confirmation message back to the serial line: "Command executed" (or "Command NOT executed"). This is commonly called an ACK/NACK reply (for "Acknowledge(d)" / "NOT Acknowledged").

Summary: in this mode, the instrument (the Slave) only send data to the serial line immediately after having been asked by the PC (the Master)
Mode 2: Asynchronous

Now suppose I started my instrument, but it is more than just a dumb sensor. It constantly monitor it's own inclination and as long as it is vertical (within a tolerance, let's say +/-15 degrees), it stays silent. If the device is tilted by more than 15 degrees and get close to horizontal, it sends an alarm message to the serial line, immediately followed by a reading of the inclination. As long as the inclination is above the threshold, it continues to send an inclination reading every 5s.

If your main program (or GUI) is constantly "waiting" for message arriving on the serial line, it can do that well ... but it cannot do anything else in the meantime. If the main program is a GUI, it is highly frustrating to have a GUI seemingly "frozen" because it won't accept any input from the user. Essentially, it became the Slave and the instrument is the Master. Unless you have a fancy way of controlling your GUI from the instrument, this is something to avoid. Fortunately, the asynchronous communication mode will let you:

- define a separate function which tells your program what to do when a message is received
- keep this function in a corner, it will only be called and executed when a message arrives on the serial line. The rest of the time the GUI can execute any other code it has to run.

Summary: In this mode, the instrument may send message to the serial line at anytime (but not necessarily all the time). The PC does not wait permanently for a message to process. It is allowed to run any other code. Only when a message arrives, it activates a function which will then read and process this message.
Mode 3: Streaming (Real time)

Now let’s unleash the full power of my instrument. I put it in a mode where it will constantly send measurements to the serial line. My program wants to receive these packets and display that on a curve or a digital display. If it only sends a value every 5s as above, no problem, keep the above mode. But my instrument at full whack sends a data point to the serial line at 1000Hz, i.e. it sends a new value every single millisecond. If I stay in the asynchronous mode described above, there is a high risk (actually a guaranteed certainty) that the special function we defined to process every new packet will take more than 1ms to execute (if you want to plot or display the value, graphic functions are quite slow, not even considering filtering or FFT’ing the signal). It means the function will start to execute, but before it finishes, a new packet will arrive and trigger the function again. The second function is placed in a queue for execution, and will only starts when the first one is done ... but by this time a few new packets arrived and each placed a function to execute in the queue. You can quickly foresee the result: By the time I am plotting the 5th points, I have already hundreds waiting to be plotted too ... the gui slows down, eventually freezes, the stack grows, the buffers fill up, until something gives. Eventually you are left with a completely frozen program or simply a crashed one.

To overcome this, we will disconnect even further the synchronisation link between the PC and the instrument. We will let the instrument send data at it's own pace, without immediately triggering a function at each packet arrival. The serial port buffer will just accumulate the packets received. The PC will only collect data in the buffer at a pace it can manage (a regular interval, set up on the PC side), do something with it (while the buffer is getting refilled by the instrument), then collect a new batch of data from the buffer ... and so on.

Summary: In this mode, the instrument sends data continuously, which are collected by the serial port buffer. At regular interval, the PC collect data from the buffer and do something with it. There is no hard synchronisation link between the PC and the instrument. Both execute their tasks on their own timing.
Automatically processing data received from a serial port

Some devices connected through a serial port send data to your program at a constant rate (streaming data) or send data at unpredictable intervals. You can configure the serial port to execute a function automatically to handle data whenever it arrives. This is called the "callback function" for the serial port object.

There are two properties of the serial port that must be set to use this feature: the name of the function you want for the callback (`BytesAvailableFcn`), and the condition which should trigger executing the callback function (`BytesAvailableFcnMode`).

There are two ways to trigger a callback function:

1. When a certain number of bytes have been received at the serial port (typically used for binary data)
2. When a certain character is received at the serial port (typically used for text or ASCII data)

Callback functions have two required input arguments, called `obj` and `event`. `obj` is the serial port. For example, if you want to print the data received from the serial port, define a function for printing the data called `newdata`:

```matlab
function newdata(obj,event)
    [d,c] = fread(obj);  % get the data from the serial port
    % Note: for ASCII data, use fscanf(obj) to return characters instead of binary values
    fprintf(1,'Received %d bytes
',c);
    disp(d)
end
```

For example, to execute the `newdata` function whenever 64 bytes of data are received, configure the serial port like this:

```matlab
s = serial(port_name);
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s.BytesAvailableFcnMode = 'byte';
s(BytesAvailableFcnMode = 'byte';
s(BytesAvailableFcnMode = 'byte';
```
With text or ASCII data, the data is typically divided into lines with a "terminator character", just like text on a page. To execute the `newdata` function whenever the carriage return character is received, configure the serial port like this:

```matlab
s = serial(port_name);
s.BytesAvailableFcnMode = 'terminator';
s.Terminator = 'CR';  % the carriage return, ASCII code 13
s.BytesAvailableFcn = @newdata;
```

Read Using serial ports online: https://riptutorial.com/matlab/topic/1176/using-serial-ports
Chapter 34: Vectorization

Examples

Element-wise operations

MATLAB supports (and encourages) vectorized operations on vectors and matrices. For example, suppose we have \( A \) and \( B \), two \( n \)-by-\( m \) matrices and we want \( C \) to be the element-wise product of the corresponding elements (i.e., \( C(i,j) = A(i,j) \cdot B(i,j) \)).

The un-vectorized way, using nested loops is as follows:

```matlab
C = zeros(n,m);
for ii=1:n
    for jj=1:m
        C(ii,jj) = A(ii,jj)*B(ii,jj);
    end
end
```

However, the vectorized way of doing this is by using the element-wise operator \( \cdot \cdot \):

```matlab
C = A.*B;
```

- For more information on the element-wise multiplication in MATLAB see the documentation of `times`.
- For more information about the difference between array and matrix operations see [Array vs. Matrix Operations](https://riptutorial.com/) in the MATLAB documentation.

Sum, mean, prod & co

Given a random vector

```matlab
v = rand(10,1);
```

if you want the sum of its elements, do **NOT** use a loop

```matlab
s = 0;
for ii = 1:10
    s = s + v(ii);
end
```

but use the vectorized capability of the `sum()` function

```matlab
s = sum(v);
```
Functions like `sum()`, `mean()`, `prod()` and others, have the ability to operate directly along rows, columns or other dimensions.

For instance, given a random matrix

```matlab
A = rand(10,10);
```

the average for each column is

```matlab
m = mean(A,1);
```

the average for each row is

```matlab
m = mean(A,2);
```

All the functions above work only on one dimension, but what if you want to sum the whole matrix? You could use:

```matlab
s = sum(sum(A))
```

But what if have an ND-array? applying `sum on sum on sum...` don't seem like the best option, instead use the : operator to vectorize your array:

```matlab
s = sum(A(:))
```

and this will result in one number which is the sum of all your array, doesn't matter how many dimensions it have.

**Use of bsxfun**

Quite often, the reason why code has been written in a `for` loop is to compute values from 'nearby' ones. The function `bsxfun` can often be used to do this in a more succinct fashion.

For example, assume that you wish to perform a columnwise operation on the matrix `B`, subtracting the mean of each column from it:

```matlab
B = round(randn(5)*10);                  % Generate random data
A = zeros(size(B));                      % Preallocate array
for col = 1:size(B,2);                   % Loop over columns
    A(:,col) = B(:,col) - mean(B(:,col)); % Subtract means
end
```

This method is inefficient if `B` is large, often due to MATLAB having to move the contents of variables around in memory. By using `bsxfun`, one can do the same job neatly and easily in just a single line:

```matlab
A = bsxfun(@minus, B, mean(B));
```
Here, `@minus` is a function handle to the `minus` operator (−) and will be applied between elements of the two matrices `B` and `mean(B)`. Other function handles, even user-defined ones, are possible as well.

Next, suppose you want to add row vector `v` to each row in matrix `A`:

```
v = [1, 2, 3];
A = [8, 1, 6
     3, 5, 7
     4, 9, 2];
```

The naive approach is use a loop (do not do this):

```
B = zeros(3);
for row = 1:3
    B(row,:) = A(row,:) + v;
end
```

Another option would be to replicate `v` with `repmat` (do not do this either):

```
>> v = repmat(v,3,1)
v =
   1     2     3
   1     2     3
   1     2     3
>> B = A + v;
```

Instead use `bsxfun` for this task:

```
>> B = bsxfun(@plus, A, v);
B =
   9     3     9
   4     7    10
   5    11     5
```

**Syntax**

```
bsxfun(@fun, A, B)
```

where `@fun` is one of the supported functions and the two arrays `A` and `B` respect the two conditions below.

The name `bsxfun` helps to understand how the function works and it stands for Binary FUNction with Singleton eXpansion. In other words, if:

1. two arrays share the same dimensions except for one
2. and the discordant dimension is a singleton (i.e. has a size of 1) in either of the two arrays

then the array with the singleton dimension will be expanded to match the dimension of the other
array. After the expansion, a binary function is applied elementwise on the two arrays.

For example, let $A$ be an $M$-by-$N$-by-$K$ array and $B$ is an $M$-by-$N$ array. Firstly, their first two dimensions have corresponding sizes. Secondly, $A$ has $K$ layers while $B$ has implicitly only 1, hence it is a singleton. All **conditions** are met and $B$ will be replicated to match the 3rd dimension of $A$.

In other languages, this is commonly referred to as *broadcasting* and happens automatically in Python (numpy) and Octave.

The function, `@fun`, must be a binary function meaning it must take exactly two inputs.

**Remarks**

Internally, `bsxfun` does not replicate the array and executes an efficient loop.

**Logical Masking**

MATLAB supports the use of logical masking in order to perform selection on a matrix without the use of for loops or if statements.

A logical mask is defined as a matrix composed of only 1 and 0.

For example:

```matlab
d = [1 0 0; 0 1 0; 0 0 1];
```

is a logical matrix representing the identity matrix.

We can generate a logical mask using a predicate to query a matrix.

```matlab
A = [1 2 3; 4 5 6; 7 8 9];
B = A > 4;
```

We first create a 3x3 matrix, $A$, containing the numbers 1 through 9. We then query $A$ for values that are greater than 4 and store the result in a new matrix called $B$.

$B$ is a logical matrix of the form:

```matlab
B = [0 0 0
  0 1 1
  1 1 1]
```

Or 1 when the predicate $A > 4$ was true. And 0 when it was false.

We can use logical matrices to access elements of a matrix. If a logical matrix is used to select elements, indices where a 1 appear in the logical matrix will be selected in the matrix you are selecting from.

Using the same $B$ from above, we could do the following:
This would select all of the elements of \( \mathbf{c} \) where \( \mathbf{b} \) has a 1 in that index. Those indices in \( \mathbf{c} \) are then set to 5.

Our \( \mathbf{c} \) now looks like:

\[
\mathbf{c} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 5 & 5 \\ 5 & 5 & 5 \end{bmatrix}
\]

We can reduce complicated code blocks containing if and for by using logical masks.

Take the non-vectorized code:

```matlab
A = [1 3 5; 7 9 11; 11 9 7];
for j = 1:length(A)
    if A(j) > 5
        A(j) = A(j) - 2;
    end
end
```

This can be shortened using logical masking to the following code:

```matlab
A = [1 3 5; 7 9 11; 11 9 7];
B = A > 5;
A(B) = A(B) - 2;
```

Or even shorter:

```matlab
A = [1 3 5; 7 9 11; 11 9 7];
A(A > 5) = A(A > 5) - 2;
```

**Implicit array expansion (broadcasting) [R2016b]**

**MATLAB R2016b** featured a generalization of its scalar expansion\(^1\) mechanism, to also support certain element-wise operations between arrays of different sizes, as long as their dimension are compatible. The operators that support implicit expansion are\(^1\):

- **Element-wise arithmetic operators:** +, -, .*, .^, ./, .\.
- **Relational operators:** <, <=, >, >=, ==, ~=.
- **Logical operators:** & , | , xor.
- **Bit-wise functions:** bitand, bitor, bitxor.
- **Elementary math functions:** max, min, mod, rem, hypot, atan2, atan2d.

The aforementioned binary operations are allowed between arrays, as long as they have "compatible sizes". Sizes are considered "compatible" when each dimension in one array is either exactly equal to the same dimension in the other array, or is equal to 1. Note that trailing singleton (that is, of size 1) dimensions are omitted by MATLAB, even though there’s theoretically an infinite

https://riptutorial.com/
amount of them. In other words - dimensions that appear in one array and do not appear in the other, are implicitly fit for automatic expansion.

For example, in MATLAB versions before R2016b this would happen:

```matlab
>> magic(3) + (1:3)
Error using +
Matrix dimensions must agree.
```

Whereas starting from R2016b the previous operation will succeed:

```matlab
>> magic(3) + (1:3)
ans =
 9 3 9
 4 7 10
 5 11 5
```

---

</tbody>
</table>

**IMPORTANT:**
Code relying on this convention is **NOT** backward-compatible with *any* older versions of MATLAB. Therefore, the explicit invocation of `bsxfun`¹,² (which achieves the same effect) should be used if code needs to run on older MATLAB versions. If such a concern does not exist, MATLAB R2016 release notes encourage users to switch from `bsxfun`:

*Compared to using `bsxfun`, implicit expansion offers faster speed of execution, better memory usage, and improved readability of code.*

### Get the value of a function of two or more arguments

In many application it is necessary to compute the function of two or more arguments.

Traditionally, we use for-loops. For example, if we need to calculate the \( f = \exp(-x^2-y^2) \) (do not use this if you need **fast simulations**):

```matlab
% code1
x = -1.2:0.2:1.4;
y = -2:0.25:3;
for nx=1:length(x)
    for ny=1:length(y)
        f(nx,ny) = exp(-x(nx)^2-y(ny)^2);
    end
end
```

But vectorized version is more elegant and faster:

```matlab
% code2
[x,y] = ndgrid(-1.2:0.2:1.4, -2:0.25:3);
f = exp(-x.^2-y.^2);
```

than we can visualize it:

```matlab
surf(x,y,f)
```

**Note1** - Grids: Usually, the matrix storage is organized *row-by-row*. But in the MATLAB, it is the...

---

¹ https://riptutorial.com/
column-by-column storage as in FORTRAN. Thus, there are two similar functions \texttt{ndgrid} and \texttt{meshgrid} in MATLAB to implement the two aforementioned models. To visualise the function in the case of \texttt{meshgrid}, we can use:

```matlab
surf(y,x,f)
```

**Note2** - Memory consumption: Let size of \(x\) or \(y\) is 1000. Thus, we need to store \(1000 \times 1000 + 2 \times 1000 \approx 1 \times 10^6\) elements for non-vectorized \texttt{code1}. But we need \(3 \times (1000 \times 1000) = 3 \times 10^6\) elements in the case of vectorized \texttt{code2}. In the 3D case (let \(z\) has the same size as \(x\) or \(y\)), memory consumption increases dramatically: \(4 \times (1000 \times 1000 \times 1000) \approx 32\text{GB for doubles}\) in the case of the vectorized \texttt{code2} vs \(\approx 1000 \times 1000 \times 1000\) (just \(\approx 8\text{GB}\)) in the case of \texttt{code1}. Thus, we have to choose either the memory or speed.
